Others have analyzed cholesterol and cholesterol esters in human serum by SFC. Kim et al.\(^{(81)}\) extracted serum with methanol–chloroform (2:1, v/v), the organic phase was collected and dried and the specimen was reconstituted in hexane. Capillary SFC was employed using a column (10 m by 50 µm ID) coated with n-octyl- and methylpolysiloxane (1:1). The mobile phase used was SF carbon dioxide with a linear pressure gradient applied over 2 h at 65 °C coupled to FID as the detector. The esters were converted to cholesterol. The method successfully accomplished baseline resolution of 10 separate cholesterol compounds. Nomura et al.\(^{(80)}\) also measured these same analytes using a packed column. Serum was processed in a very similar manner, employing methanol/chloroform to extract the cholesterols. Specimens were reconstituted in 50 µL of hexane of which 1 µL was injected. The column was 250 mm by 4.6 mm ID, packed with 5 µm octadecylsilanol bonded particles, and the mobile phase was SF carbon dioxide maintained at 45 °C and 200 atm. Detection was by FID with the run requiring about 20 min. Sjörberg and Markides have recently interfaced SFC with atmospheric-pressure chemical-ionization MS and applied it to cholesterol and fatty acids.\(^{(99)}\) Laasko and Manninen have also recently interfaced SFC with atmospheric-pressure chemical-ionization MS to measure lipids.\(^{(100)}\) Using a nonpolar packed column they achieved excellent separation of both saturated and unsaturated triacylglycerols. This approach may be readily adapted to more physiological specimens.

### 4.5 Comparisons with Other Methods

As described throughout, SFC has several favorable chromatographic properties that provide it with a versatility and chromatographic efficiency that compare well with and in many cases exceed other instrumental approaches. The cost for SFC systems and their operation are somewhat, though not dramatically, higher than GC or HPLC systems. The variety of detectors that can be interfaced with SFC continues to grow, affording more sensitive and selective assays. However, the limited use of any of these instruments in the clinical laboratory currently may perpetuate the status quo given the increasing pressures for laboratories to adopt standardized methodologies used widely at many institutions, and a regulatory environment that discourages method development by individual laboratories themselves. Although automated instruments are in high demand in the hospital setting, most of these are systems developed around the concept that each analyte is measured by a single assay involving unique reagents, whether immunological, enzymatic, or colorimetric. That is to say instruments generally used in laboratories do not rely on separation efficiencies and characteristic retention times to provide isolation of an analyte from other matrix components which can be uniquely delivered to a universal detector. Although SFC provides this added selectivity, such approaches are foreign to most clinical laboratorians and will require education to broaden their perspectives. Additionally, the attractiveness of SFC would be greatly enhanced if sample introduction methods improve sufficiently to allow the capture of most of the analyte in a specimen and thereby increase assay sensitivity. Finally, the general lack of SFC method development specifically for clinical chemistry has been a barrier to its broader use.

### 5 Future Developments

The future for SFC is bright. Even in clinical chemistry, rapid and sensitive detection instruments now offer increased specificity and sensitivity while managing large numbers of rapidly eluting analytes from complex matrices such as serum or plasma. Some state-of-the-art systems are expensive and may be beyond the...
current resources of hospital laboratories. Consequently the financial means to take advantage of the remarkable potential of SFC seems more likely to reside with commercial reference laboratories, pharmaceutical companies, or analytical instrument companies, which may also create new markets for their services or products in this area. The vast number of broadly used, competitively priced, off-the-shelf assays already marketed specifically to clinical laboratories means that SFC will initially need to develop niche markets, such as in toxicology, assessment of environmental contaminant exposure, and/or therapeutic drug monitoring. It is also incumbent on researchers who develop SFC techniques to apply them more rigorously to clinical chemistry targets, using actual specimens and providing sufficient numbers of assayed patient and control materials to validate these promising methods.

Ultraviolet/Visible Light Absorption Spectrophotometry in Clinical Chemistry

Stephen L. Upstone
Perkin Elmer Ltd., Beaconsfield, UK

1 INTRODUCTION

Ultraviolet/visible (UV/VIS) absorption spectroscopy has been used in the clinical laboratory for many years. The technique has appeal, as it is almost universal in its application. Although much of the routine work is performed using high-throughput dedicated clinical analysis systems, absorption spectroscopy still has a place in most clinical laboratories.

This article discusses the range of application types for which absorption spectroscopy can be used and some examples of common analyses are given. The article also discusses the merits of various instrument types and discusses some more advanced spectroscopic techniques, such as derivative spectroscopy, to enhance the data measured by the spectrophotometer. Brief reference is also made to the use of reflectance in clinical analysis.

1 INTRODUCTION

Ultraviolet/visible (UV/VIS) absorption spectroscopy has been used in the clinical laboratory for many years. The technique has appeal, as it is almost universal in its application. Although much of the routine work is performed using high-throughput dedicated clinical analysis systems, absorption spectroscopy still has a place in most clinical laboratories.

This article discusses the range of application types for which absorption spectroscopy can be used and some examples of common analyses are given. The article also discusses the merits of various instrument types and discusses some more advanced spectroscopic techniques, such as derivative spectroscopy, to enhance the data measured by the spectrophotometer. Brief reference is also made to the use of reflectance in clinical analysis.
I have spent some length explaining the fundamentals of the technique and about instrument design. This is deliberate – too often people treat UV/VIS spectrophotometers as a simple “meter” without understanding their limitations or suitability for a particular analysis. This article should also be useful for understanding spectrophotometric assays on dedicated analyzers.

2 PRINCIPLES OF ANALYSIS AND INSTRUMENT PARAMETERS

2.1 Fundamentals of Ultraviolet/Visible Spectroscopy and the Beer–Lambert Law

UV/VIS spectroscopy is the study of how a sample responds to light. When a beam of light passes through a substance or a solution, some of the light may be absorbed and the remainder transmitted through the sample. The ratio of the intensity of the light entering the sample \( (I_0) \) to that exiting the sample \( (I_t) \) at a particular wavelength is defined as the transmittance \( (T) \). This is often expressed as the percentage transmittance \( (%T) \), which is the transmittance multiplied by 100 (Equation 1):

\[
%T = \left( \frac{I_0}{I_t} \right) \times 100 \tag{1}
\]

The absorbance \( (A) \) of a sample is the negative logarithm of the transmittance (Equation 2):

\[
A = -\log T \tag{2}
\]

The UV/VIS range of the electromagnetic spectrum covers the range 190–700 nm (most instruments are capable of measuring at longer wavelengths than this, depending on their detector type). For clinical analysis this is useful, as water (most assays are in aqueous solution) is almost completely transparent in this region. Most clinical assays are concerned with quantitation rather than identification (there are more powerful techniques available to perform the latter) as absorption spectra tend to be featureless – they lack the fine structure which is found, for example, in an infrared (IR) spectrum. Some techniques to enhance resolution and qualitative information will be discussed later.

The most important principle in absorption analysis is the Beer–Lambert law. This law states that, for a given ideal solution, there is a linear relationship between concentration and absorbance provided that the path length is kept constant; the absorptivity \( (\varepsilon) \) is a constant for each molecule for each wavelength (Equation 3):

\[
A = \varepsilon cl \tag{3}
\]

where \( \varepsilon \) = the absorptivity of the substance, \( c \) = concentration and \( l \) = path length. Provided that \( \varepsilon \) and \( l \) are kept constant for a given set of experiments, a plot of the sample absorbance against the concentration of the absorbing substance should give a straight line. In practice, a calibration curve is prepared by plotting the absorbance of a series of standard samples as a function of their concentration. If the absorbance of an unknown sample is then measured, the concentration of the absorbing component can be assessed from this graph. Another consequence of the Beer–Lambert law is that it is possible to change the path length to affect the absorbance. This can be useful where lower detection limits are required as the path length can be increased (longer path length cuvettes are available) or, where the absorbance is too high to be measured on the instrument, the path length can be reduced. Alternatively, it is possible to reduce the absorbance by diluting the sample, but one has to take care when dealing with biologically active samples, particularly enzyme-based solutions, as this may have a profound effect on the activity.

2.2 Linearity and Deviations from the Beer–Lambert Law

Above, the Beer–Lambert Law has been shown to be a linear relationship between sample concentration and absorbance. If this relationship is tested experimentally by measuring samples of increasing concentration and the results are plotted, the relationship will be seen to break down with increasing absorbance. With general laboratory UV/VIS spectrophotometers of recent design, this will probably be around 3 absorbance units (AU).

What is observed here is not a breakdown in the Beer–Lambert law (although some assumptions about the sample being infinitely dilute are made in the law) but a limitation in the instrument’s performance.

The greatest contributor to this nonlinearity is the instrument’s stray light. Stray light can be loosely defined as the amount of light present in the instrument at nonanalytical wavelengths or, put another way, the amount of unwanted light present in the system. This unwanted light can come from several sources. First, there may be light from outside entering the optical system. Manufacturers usually go to some lengths to exclude this light and so it ought to be negligible in a well-designed instrument. The main source of stray light comes from the monochromator itself.

Monochromators (in dispersive instruments) are usually diffraction gratings. These gratings, although highly efficient producers of monochromatic radiation, are not entirely efficient. They will also allow small amounts of light to pass through at other discrete wavelengths, in addition to small amounts of white light. We have seen
earlier that absorbance is a logarithmic scale and so 1 AU corresponds to 10% T, 2 AU corresponds to 1% T, 3 AU to 0.1% T and so on.

If the light throughput is expressed in percentage terms (%T) and a stray light value (from the instrument manufacturer’s data) of 0.05% transmittance is quoted, this will represent a third of the total light seen by the detector at 3 AU (i.e. 0.1% T). This will cause an underreporting of the true absorbance. By 4 AU (0.01% T), there will be more stray light than sample signal, rendering the instrument unusable at this value. Table 1 shows the anticipated effect on the observed absorbance for a range of stray light values which may be encountered on various instruments found within the clinical laboratory.

<sup>a</sup> Low-cost or old instrument.
<sup>b</sup> High-performance double-beam instrument.
<sup>c</sup> "Top of the range" double-monochromator, double-beam instrument.

Another possible reason for nonlinearity is sample scatter. The instrument expects light to travel through the sample in a straight line (unless there is special provision in the instrument design). If the sample is turbid, this light will be scattered and the light will be splayed out in a cone-like fashion. As a result, less light will fall on the detector and a falsely high absorbance reading will be observed. Turbidity is relatively easy to observe as it is not wavelength specific. A scattering sample, therefore, will have a raised baseline. In bad cases, the baseline may be elevated over 1 AU.

#### 2.3 Cuvettes and Solvents

Apart from ensuring that the instrument design is sufficient for the required analysis, the user must also check that the other components of the analytical system – the cuvettes and the solvents – are applicable for the required task. Cuvettes are offered in either optical glass or quartz. Optical glass will transmit light above 320 nm whereas quartz will transmit light well below 190 nm (the usual low-wavelength limit for UV/VIS spectrophotometers).

As an alternative to glass and quartz cuvettes, several manufacturers offer disposable cuvettes. These are made from various plastics including polystyrene and acrylic. These cuvettes offer the main advantage that they do not need cleaning between samples, which is very useful when handling biohazardous samples. The disadvantages are that they have a restricted wavelength range (one should carefully check the manufacturer’s stated wavelength specification before using disposable cuvettes) and they have a lower optical performance. In some cases striations across the face of the cuvette might be observed. These are due to the molding process in the cell manufacture. There will also be a molding mark at the bottom of the cuvette (from the extrusion process) and this can make stirring with a small magnetic flea difficult (with instruments which provide a stirring facility). Another disadvantage with disposable cuvettes is that the cell path length (an important consideration for the Beer–Lambert law) will not be as accurate as with glass or quartz cells and this may have quantitative accuracy implications.

As regards solvents, water has the widest range and the lowest cutoff wavelength. Cutoff wavelengths are somewhat arbitrary and there will be variations in the stated values from different literature sources. I have used the definition as being the wavelength
at which a 1-cm cuvette filled with pure solvent has a transmittance of 10% (equivalent to 1 AU). The cutoffs for common solvents are given in Table 2. Some buffers [e.g. tris(hydroxymethyl)aminomethane (TRIS)] have organic components and so it should not be assumed that the cutoff is identical with that for water.

2.4 Resolution (Band-pass) and Slit Width

UV/VIS instruments have a specified band-pass. This term relates to the instrument’s ability to resolve peaks which are very close together or “shoulders” (small features on the side of a larger peak). The band-pass will either be fixed, usually between 1 and 2 nm, or, in the case of more expensive instruments, variable (either continuously or in finite steps). Photodiode-array instruments have a fixed optical band-pass as there is no physical slit aperture on these instruments (although the software may be able to simulate other slit conditions); the resolution is defined by the light dispersion, the polychromator and the number of elements in the array.

The band-pass will affect the instrument’s ability to discriminate between sharp features. Most molecules possess a broad spectrum, so a small band-pass will not change the appearance of the spectrum (apart from increased noise). Some molecules commonly encountered in clinical analysis, such as porphyrins and the various types of hemoglobin (oxy-, met- and carboxy-) give sharp structures and the position of the peak has to be accurately measured or a misdiagnosis may otherwise result.

Figure 2 shows the effect on a sample with fine structure, i.e. benzene vapor in a sealed cuvette. This is a highly artificial situation, as typical samples in the clinical laboratory do not exhibit such sharp features.

Figure 3 shows the effect of variable resolution on a more typical sample with a single broad peak. In this instance there is little or no difference between a high- and low-resolution (band-pass) scan.

**Figure 2** Effect of changing the instrument resolution on a sample with sharp peaks (benzene vapor) showing the effect on band shapes and illustrating sharper discrimination using a 0.5-nm slit (b) compared with a 2-nm slit (a).

![Figure 3](image3.png)

**Figure 3** Effect of using various slit settings on a typical spectrum with broad bands (spectra offset for clarity) showing that the slit setting is largely irrelevant for broad peaks.
2.5 First- and Second-derivative Spectroscopy

UV/VIS spectra are rather featureless at room temperature, which is why the technique is primarily used for quantitative analysis rather than for sample identification purposes. A broad ultraviolet (UV) spectrum is composed of many separate electronic transitions which, at room temperature, become “blurred” to give the appearance of a single entity. Spectra only become more defined at very low temperatures and in the gas phase. Neither of these two conditions is applicable in routine clinical analysis.

One major advantage that UV/VIS analysis possesses for biological measurements is that water (which is the main component of all living systems) is virtually transparent across the entire range (there is some very weak activity around 860 nm) and so any technique to improve the qualitative data is welcome.

Derivative spectroscopy is a useful tool to give some improvement. As the name suggests, the technique consists of plotting the rate of change of the absorbance spectrum versus wavelength. This will give a plot (shown in Figure 4 with the original spectrum). At peak maxima and minima (and also points of inflection), the graph is seen to pass through zero on the ordinate. As a result, the technique can be used to identify peak maxima and minima. This is termed a first-derivative spectrum.

First-derivative spectra have their uses but they are difficult to interpret (as the brain often sees the ‘peaks’ rather than the true information). If we take the second-derivative spectrum (by derivatizing the absorbance spectrum twice), we obtain a plot such as that in Figure 5.

The second-derivative spectrum can be thought of as an inverted spectrum. Sharp peaks will be made even sharper. Broad peaks (and also broad background features) will become flattened and so the technique can be used both as a peak-enhancement and background-rejection tool. The second-derivative spectrum, like its absorbance counterpart, still contains quantitative information. If two points are consistently used on the spectrum and the difference in their values on the ordinate is taken, this can be plotted against concentration and a linear relationship established.

Derivative spectra represent an alternative presentation of the original data. Information cannot be created and so there is a cost involved. This cost is at the expense of a much poorer signal-to-noise ratio (as the noise is also being derivatized) and so if a requirement for derivative spectroscopy is anticipated, an instrument with a good noise specification is highly desirable. Single-beam instruments should not be considered for serious derivative spectroscopy.

Higher order derivatives also are possible, and usually up to the fourth derivative is offered on current instrumentation, but the increased noise makes their general analytical use questionable.

2.6 Verification of Spectrophotometer Performance

Clinical analysis is concerned with producing an accurate result to enable the clinician to make an accurate diagnosis and to provide the correct treatment. It is important, therefore, that all equipment used to make the diagnosis is well maintained and that the operators have a sufficient skill level to understand the limitations of the instrument and to use the correct operating and sampling procedures.

Instruments should be checked regularly, using a certified reference material (CRM). As a minimum, the user should possess a sample for checking wavelength
accuracy and a set of absorbance filters. Wavelength standards should never be used to check absorbance accuracy and vice versa. Wavelength standards (such as holmium oxide glass filters) have very sharp peaks whereas absorbance standards such as the National Institute of Standards and Technology (NIST) 930D filters are of neutral density.

Additional checks such as for stray light and noise may also be advantageous. Most instrument companies will be able to give advice on instrument performance checks and routine maintenance.

Microplate reader users are more limited in the choice of calibration aids. For filter-based instruments (the majority at the time of writing), there is no way to check wavelength accuracy (other than to scan the filter on a spectrophotometer) and there are few CRMs available for all formats of microplates. If one is using a microplate reader, the manufacturer should be contacted for advice.

3 OVERVIEW OF INSTRUMENT DESIGNS AND THEIR ADVANTAGES AND DISADVANTAGES

3.1 Dispersive and Diode-array Systems

Before going into details of analysis, it is important to discuss the design of a UV/VIS spectrophotometer and the implications of the various design types for a particular analysis, and to understand the limiting factors in making that measurement.

UV/VIS instruments are available in two main types, dispersive and photodiode array (usually shortened to diode array). The dispersive design uses a monochromator before the sample to convert the white light produced by the light source into a single pure wavelength of light. This single wavelength is then passed through the sample and detected. The monochromator can be either a fixed-wavelength filter or a variable-wavelength design such as a prism (rare nowadays) or a diffraction grating. On higher specification instruments, there may be two monochromators linked in series to permit higher performance – particularly at high absorbance values (e.g. over 3.0 AU).

3.2 Dispersive Ultraviolet/Visible Spectrophotometers

Dispersive UV/VIS spectrophotometers have four main optical configurations:

- single beam
- double beam (single detector)
- dual beam (dual detector)
- photodiode array.

3.3 Single-beam Spectrophotometers

The single-beam spectrophotometer is the simplest optical configuration. It consists of a light source, monochromator (either a grating or a filter), the sample area and the detector, as shown in Figure 6. In the single-beam design, it is necessary first to zero the instrument (to establish the I₀ value) and then to measure the sample.

Single-beam instruments are used mainly on grounds of cost. They have poorer noise specifications compared with their dual- and double-beam counterparts and are prone to drifting with time. This makes accurate kinetics and applications involving repetitive sampling over time more difficult. The cheaper models often lack the spectral resolution demanded by some clinical applications (e.g. porphyrin analysis).

3.4 Double-beam Spectrophotometers

In the double-beam design as shown in Figure 7, there is still a single detector – usually a photomultiplier (a phototube). The beam is then sent alternately through sample and reference positions using a chopper wheel or vibrating mirror. The electronics in the instrument are also able to synchronize the beam switching with the detector so that it can distinguish whether the detector is measuring the sample or reference beam at any one time.

Even in complete darkness, a photomultiplier will output a signal. This is known as the dark current. As a result, the beam shuttling device will also have some means of temporarily blocking the light from both beams so that this residual signal (the dark current) can be measured and subtracted from each sample and reference measurement.

![Figure 6 Single-beam optical configuration.](image-url)
Figure 7 Double-beam (chopper wheel) optical layout.

Figure 8 Dual-beam spectrophotometer optical layout.
3.5 Dual-beam Spectrophotometers

An alternative to the double-beam design is the dual-beam layout (Figure 8). In this design, the beam is split using a half-silvered mirror (beam splitter) into its sample and reference components. Each beam has its own detector.

This design is only practical with solid-state detectors (which have fairly constant dark current) and gives equivalent results compared with a double-beam system for most analyses. The design removes the need for a mechanical beam shuttling device (and hence improves reliability) and, as solid-state detectors are used; there is no need for a high-tension power supply to provide the high voltages (around 1000 V) which are required to set the photomultiplier gain. The design also produces very good baseline noise characteristics as, again, there is no contribution from the mechanical beam shuttle. If the design has a weakness, it is at very high absorbance (over 3 AU) as the photomultiplier is able to detect lower light levels than solid-state detectors. Routine clinical analyses rarely exceed these absorbance values and, in any case, a single monochromator instrument is limited by its stray light (see later). If samples exceed the upper absorbance limit of a spectrophotometer, they can either be diluted or a shorter path length cell can be used.

3.6 Photodiode-array Spectrophotometers

Photodiode-array spectrophotometers have been available since the early 1980s with the advent of the early designs from Hewlett-Packard (now Agilent) (Figure 9). The design is basically a single-beam instrument but the sample is irradiated with white light (as opposed to monochromatic light in a dispersive instrument). This light, after it has passed through the sample, is then dispersed by a dispersion monochromator (often referred to as a polychromator) on to a special solid-state detector with individual segments, one for each wavelength. The main appeal of these instruments is that the measurement of a spectrum takes only a few seconds. The system has some disadvantages, however. A diode-array spectrophotometer is a single-beam instrument (although a nonanalytical wavelength may be used as a pseudo-reference to overcome nonwavelength-specific drift). It is also less suitable for some single-wavelength measurements as a whole spectrum has to be collected irrespective of whether the data points are required or not. The design is also more prone to errors from sample fluorescence (as the sample irradiation is at all wavelengths and so any fluorophore present will be also excited) and any nonparallel surfaces in the sample (as this will affect the beam dispersion on to the individual elements in the array). Nevertheless, the diode-array system offers a high throughput of scanned data and the ability also to visualize whole spectrum for single-wavelength analyses so that any unexpected results can be investigated further.

3.7 Microplate Reader Spectrophotometers

Over the past 20 years, many clinical analyses have been transferred from the traditional, cuvette-based spectrophotometer to a microwell (normally 96-well) format. The microwell started life in the early 1960s for microbiological culture. Later, it was realized that the format could be applied to bulk analysis using clear microplates and a dedicated reader.

Microplates are manufactured from plastic (usually polystyrene or acrylic, depending on the required wavelength range). They are cheap, disposable and provide a universal format. The plates also have the advantage that they are compatible with liquid handling devices such as plate fillers and washers.

Although 96 wells is the most common format, the requirement for greater speed and throughput has seen the introduction of even higher density formats such as 384 wells per plate.

The dedicated reader is really a spectrophotometer in an applied form. Most plate readers work in the visible region only (as the polystyrene microplates absorb in the UV region) and use optical filters rather than monochromators. More sophisticated readers may also offer multiple reading modes such as fluorescence and bioluminescence in addition to absorbance. Many modern readers can also be used in conjunction with a robotic system.

In terms of performance, there is a compromise compared with using a spectrophotometer, but for many assays this is far outweighed by the reduced costs and greater convenience which this format offers.
3.8 Reflectance-based Analyzers

In recent years, reagent manufacturers have investigated ways of making tests even more simple to perform and less dependent on expensive analytical equipment. An example of this is the portable glucose monitoring systems which diabetics use to check their blood sugar levels.

The color reaction is performed on a solid support which is coated with the required reagents. This support is usually a small stick or strip. After exposure to a blood or urine sample, this support is inserted in the analytical device and the reading displayed. These devices are based on reflectance rather than absorbance (as the supports are opaque it is not possible to pass light through them).

When light falls on a surface it can be reflected in two main ways, as either specular or diffuse reflectance. Specular reflectance (from the Latin word speculum for mirror) is the study of mirror-like reflectance. The path of the reflected ray of light is entirely predictable as it should be at the same angle as the angle of light incidence. In diffuse reflectance, the surface has a matt surface which scatters the reflected light in all directions and this scattered reflectance can be collected by a detector. In practice, a sample may exhibit both types of reflectance (e.g. a coating with a glossy surface) and so the geometry of the collection sphere can be adjusted either to include or exclude the specular component. Reflectance is normally expressed as a percentage compared with a standard – normally a white surface such as Teflon®.

The relationship between reflectance and concentration is much less clearly defined when compared with absorbance as there are physical factors to consider (e.g. particle size, layer thickness). A fairly accurate quantitative result can be obtained by taking the logarithm of reflectance or by using the Kubelka–Munk equation. Manufacturers of reflectance-based devices need to spend considerable development work in providing an accurate calibration which can be stored inside the instrument to produce the correct results. These results will need to be verified by regulatory bodies such as the US Food and Drug Administration (FDA) before such a device can be marketed.

As many of these devices are designed for use in the home or general practitioner’s surgery, they must be manufactured as cheaply as possible. As a result, an LED can be used in place of a light source and monochromator. Detection is by means of a silicon photodiode or other solid-state detector. A diagram of a reflectance-based analyser for the measurement of blood sugar for diabetes monitoring is shown in Figure 10.

4 COMMON CLINICAL APPLICATIONS USING ULTRAVIOLET/VISIBLE ABSORPTION SPECTROSCOPY

There are many clinical tests which employ UV and visible spectrophotometry. For readers who want a detailed and exhaustive list, there are many textbooks on the subject. In this section I have highlighted a range of these tests and detailed how they work.

4.1 Enzyme Rate Assays

Enzymes are biocatalysts, which are extremely efficient in converting their chosen substrates into product. Apart from their efficiency, they are also highly specific and often will not work with a slightly different substrate. Often it is useful to study the rate of this catalysis by measuring either the rate of depletion of substrate or the formation of products. This may be a matter of simply measuring the absorbance of one of the reaction components directly or by forming an absorbing conjugate with another molecule.

Enzyme kinetics are usually zero order. This means that, after an initial lag phase, there should be a linear relationship between substrate (or product) concentration with time until one of these components becomes limiting. It is therefore useful if the instrument software is able to allow the user to choose where this linear portion is (either prior to or, better, after data collection) and to use this portion to calculate the rate. The enzyme activity is normally expressed in International Units (IU) by applying a simple factor to the measured slope (absorbance/time).

Enzyme rate assays are nearly always performed at a single wavelength (340 and 405 nm are commonly used) and require a temperature-controlled environment. This may take the form of a simple water-jacketed cell holder where water (or other liquid) is passed through the water jacket at a constant temperature (supplied by a thermostated water circulator). Some cell holders use thermoelectric (or Peltier effect) cell holders. These cell...
holders have the advantage of much more precise temperature control and the ability to work below ambient temperatures (Peltier cells can cool by reversing the electric current flow). Some Peltier designs, particularly those requiring high or low temperatures, will still require a flow of cold water in order to operate correctly whereas those covering a more restricted range do not.

Most enzyme reactions are fairly slow, taking place for 5 min or more. In order to increase productivity, most UV/VIS instruments offer a cell changer as an accessory. This is a shuttle device, which can hold six or more cuvettes at once. The instrument then cycles through each of the cell positions taking a reading on each cell every 30 s during the course of the reaction.

The collected data can be analyzed either using the instrument’s own kinetic software or externally, using either a computer or manual calculation. Some statistical data on the quality of the curve fit are also useful.

An example of a clinical rate assay is the determination of butyrylcholinesterase (BchE). Certain individuals express a mutant form of the BchE gene. This then encodes for a defective form of the enzyme, which lacks the ability to hydrolyze succinylcholine. In some rare cases, the complete BchE gene is missing. A defective or missing gene will not, normally, be of any consequence. If, however, succinylcholine is used during tracheal intubation in the administration of inhalation anesthetics, this will then cause the patient to undergo complete paralysis. The test for this enzyme is commonly performed using a UV/VIS spectrophotometer with a temperature-controlled cell holder (most tests will be performed at 37 °C).

One important class of enzyme-catalyzed reactions involves the oxidation and reduction of pyridine nucleotides [nicotinamide adenine dinucleotide (NAD +) and nicotinamide adenine dinucleotide (reduced form) (NADH), respectively]. If the reaction is followed at 340 nm, NAD + does not absorb whereas NADH shows a strong absorbance. Examples of NAD +/NADH kinetic reactions include glucose dehydrogenase, aspartate aminotransferase and amylase.

Other enzymatic tests often include a colorless compound, which is added to the reaction. This is then enzymatically converted to a colored product (e.g. p-nitrophenol). Examples of this type of test include alkaline phosphatase, acid phosphatase and urea.

altered wavelengths for each analyte. As with rate assays, the test may be based on reading the analyte directly or an additional color reaction may be required to develop the test.

4.3 Immunoassays, Enzyme-linked Immunosorbent Assays and Microplate Assays

Immunoassays rely on the very strong affinity between an antibody and its target molecule (antigen). This strong affinity has been used to design a wide range of assays for a variety of targets. These include pathogens (where a chemical associated with the organism or virus will be targeted), tumor markers and drug monitoring (either therapeutic or drugs of abuse). In fact, anything which can elicit an antibody response can be developed into an immunoassay. These assays are ideal where high specificity is required. They are not good at dealing with a range of possible compounds. For example, it is difficult to design an immunoassay to detect all abused drugs, only specific types. If a “designer” drug is synthesized with an additional functional group, this may adversely affect the assay.

Immunoassays are competitive assays. The reaction mixture will contain antigens labeled with some kind of tag (this is either a radiolabel, a fluorophore or a site which will bind to a chromophore). When the (unlabeled) sample antigens are introduced, there will be competition between the labeled and unlabeled antigens and this can be calibrated against a binding curve (which will be sigmoidal in nature). Prior to measurement, it will be necessary to separate the free and bound antigens and so a separation step will be required (heterogeneous assay). Much effort has been spent in previous years trying to simplify this process (e.g. using magnetized, latex-covered beads) or using a technique which inherently separates bound from unbound antigens (e.g. fluorescence polarization) to produce a homogeneous assay. For the highest sensitivity immunoassays, either radioactivity or fluorescence (or time-resolved fluorescence) has to be used. In situations where lower sensitivity is acceptable, an absorption-based assay can be employed.

A popular assay type is the enzyme-linked immunosorbent assay (ELISA). In this assay, an antibody (specific to the analyte) is coated on the bottom of the microplate. In some cases, any exposed area on the microplate (i.e. any area where the antibody has not been coated) is blocked using bovine serum albumin (BSA) and the excess antibody is washed away. The blocking agent is to help prevent unbound antigen from adhering directly to the plate, thus affecting the final result.

The analyte and enzyme conjugate [e.g. horseradish peroxidase (HRP)] is added. The analyte will bind to the antibody, which has previously been coated on the microplate. The enzyme conjugate also binds to the analyte. This will be used later in conjunction with a specific dye to produce the color, which will then be measured on the reader.

4.4 Porphyrin Analysis

Porphyrin is the name given to a number of related conditions, some genetic, which result from an over production of porphyrins, which are precursors in the production of hemoglobin. Sufferers are prone to bouts of severe abdominal pain, vomiting, severe personality changes and sensitivity to light. Some types of porphyria produce characteristic dark-colored (“port wine”) urine and this is a good first indication that porphyria is present.

One of the main types of porphyria (a generic term for porphyrin-related disease) is variegate porphyria. In this case a mitochondrial enzyme called protoporphyrinogen oxidase is defective (owing to incorrect genetic coding) and as a result excess protoporphyrin (one of the porphyrin types) is produced. The protoporphyrinogen reacts with oxygen to produce protoporphyrin in an uncontrolled reaction. Other porphyria types include acute intermittent porphyria. Accurate diagnosis of the exact type of porphyria is vital as incorrect treatment could have very serious consequences.

Porphyrins\(^\text{(17)}\) have a characteristic UV/VIS absorption peak (Soret peak) in the region 400–410 nm depending on the type of porphyrin present (coproporphyrin has a peak between 402 and 403 nm whereas the uroporphyrin peak lies between 406 and 407 nm).

The urine sample is filtered, diluted with distilled water and acidified with hydrochloric acid. The sample is scanned between 300 and 500 nm and the spectrum peak positions are noted. The measurement is taken by first constructing a baseline at points at either side of the main peak (usually around 380 and 430 nm) and then measuring the height of the peak down to this baseline (Figure 11).

![Figure 11 Porphyrin analysis using three wavelengths.](image)
The total porphyrin concentration is given by Equation (4):

\[
\text{total porphyrin} \left( \mu\text{g} \text{L}^{-1} \right) = 2A(\lambda_{\text{max}}) - (A_{380} + A_{430})\varepsilon
\]

(4)

where \( A \) is absorbance, \( \lambda_{\text{max}} \) is the wavelength at maximum absorption and \( \varepsilon \) is the molar absorptivity (a constant) for the analyte; for porphyrins (in a 1-cm cell) \( \varepsilon = 4740 \mu\text{g L}^{-1} \).

Alternatively, second-derivative spectroscopy has been used\(^{(1)}\) (as this reduces background effects and produces sharper peaks). It should be borne in mind that, for a full and correct diagnosis, the type of porphyrin must be accurately identified. This can only be done using a good UV/VIS spectrophotometer offering narrow slits and a skilled user, as interpretation of the corrected spectrum or the second-derivative spectrum may be involved. UV/VIS absorption spectroscopy is generally used for screening and other techniques such as high-performance liquid chromatography (HPLC) or fluorescence spectroscopy (which gives much better selectivity as each porphyrin has a different excitation and emission wavelength) are often used to make the final, confirmatory diagnosis. These techniques are usually offered by porphyria reference centers.

4.5 Hemoglobin Analysis

Hemoglobin is a protein with a nonprotein core consisting of an iron atom surrounded by heme groups. It has remarkable oxygen transportation properties where it can change its conformation to accept oxygen (oxyhemoglobin). This process can be inhibited by carbon monoxide, which has a 200 times stronger affinity for hemoglobin (carboxyhemoglobin) than oxygen, resulting in severe respiratory problems and death in cases of carbon monoxide poisoning. Hemoglobin possesses an iron atom core in its ferrous (Fe\(^{2+}\)) state. If the iron is oxidized to its ferric (Fe\(^{3+}\)) state, its oxygen transport capabilities are diminished and the molecule is called methemoglobin (metHb).

Total hemoglobin can be measured by performing a reaction of the total hemoglobin present with potassium cyanide to form a hemoglobin–cyanide complex (Figure 12).

This complex has a peak around 546 nm, which can be measured and quantitated.

Franzini et al.\(^{(21)}\) have described a method based on second-derivative spectroscopy to measure hemoglobin and its homologs. This method helps to overcome the interference from bilirubin, which is also often present in these analyses.

Shih et al.\(^{(22)}\) also used multicomponent analysis in order to quantitate carboxy-, met- and oxyhemoglobin independently from a single scan. This is a statistical approach which compares each data point in a spectrum with a calibration set of known references—either mixtures or single components—and attempts to calculate the relative proportions of each in the unknown spectrum. This approach has its attractions as it is potentially able to measure each component without the need for a separation step. The main drawback is when there is significant spectral overlap or in situations where the concentrations of the various components differ widely. Problems may also occur if there is a strong background matrix which is not constant. More powerful techniques exist, such as principle component regression or partial least-squares fitting. These techniques are a science in themselves (chemometrics) and go beyond this article.

4.6 Protein Assays

Proteins are composed of amino acid building blocks. Protein has some intrinsic absorbance at approximately 280 nm (from the aromatic amino acids—tyrosine and tryptophan) but it is more common to perform a reaction to produce a colored complex which can be assayed in the visible region. The three most common procedures for protein analysis are biuret, Bradford and bicinchoninic acid (BCA) assays.

Table 4 lists the various protein methods. These are all simple colorimetric determinations.

is calculated. Optionally, a third reference point can be taken at 320 nm (to assess the amount of turbidity and scatter) and this absorbance value can be subtracted from either of the two absorbance values prior to calculating the ratio. If the ratio of the two absorbances is between 1.7 and 2.0, then the DNA preparation is considered to be pure. If it is >2, then there is probably a high RNA content. A lower ratio would indicate a high protein or phenol content (a reagent commonly used in DNA extraction).

One major issue in molecular biology is sample volume. It is not uncommon to have volumes of 10 µL and so special low-volume cells are available. These special cuvettes are made from quartz (as plastic and glass cuvettes generally absorb below 300 nm). Dedicated low-cost instruments are available for the assessment of nucleic acid purity.

ACKNOWLEDGMENTS

I thank Hanswilly Müller at PerkinElmer, Überlingen, Germany, for providing some of the spectra shown here, Jackie Woolf at the Porphyria Reference Centre, Heath Park Hospital, Cardiff, and Ipswich Hospital, UK, for some information and spectra of porphyrins and Chris Royle at the Brompton Hospital, UK, for keeping me up to date with the latest developments in clinical analysis. I also thank Agilent Technologies (formerly Hewlett-Packard Instruments) and Hypoguard for permission to use their diagrams.

The chemical analysis of urine and other body fluids is an integral part of laboratory medicine today. Clinical chemistry measurements are made in laboratories ranging from large medical research/teaching centers to small rural physicians’ offices, and with varying degrees of sophistication in all parts of the world. Indeed, the use of chemical tests at home is currently an important part of monitoring chronic conditions such as diabetes, and this aspect of chemical testing is expected to expand.

This article traces the historical methods of urine testing to provide information on health and disease, from crude visual examination in ancient times to modern techniques using sophisticated chemical instrumentation. The information obtained is useful in the diagnosis of disease, in monitoring the course of the treatment of disease, and in helping to maintain wellness in normal populations.

The chemical tests most widely used in urinalysis are described in some detail along with a discussion of the development of commercial tests leading to the evolution of the diagnostics industry. Chemical tests on other bodily fluids are briefly summarized.

1 INTRODUCTION

Urinalysis has helped throughout the ages to diagnose disease. We briefly review the history of its development, from primitive urinalysis consisting mainly of observation of specimens to modern uses of chemical reagents and automated instrumentation. An older but more detailed presentation is found in our book, Urinalysis in Clinical Laboratory Practice. With the creation of the diagnostics industry, the application of analytical chemistry to the diagnosis of disease has allowed the clinical laboratory to provide more precise, more accurate, more useful and more rapid information to the physician. Moreover, chemistry allows the patient to monitor chronic conditions such as diabetes directly and thus assume more responsibility for his or her own health. Because the analysis of urine does not require invasive specimen collection procedures, the immediate future appears bright for its continuing utility. It also seems that the kidney’s role in excreting a variety of metabolites assures urinalysis a continuing place in analytical chemistry.

2 HISTORY OF URINE TESTING

The practice of using information from urine testing to indicate disease or abnormalities begins in ancient times,
2.1 Ancient Times

Before there was written language, symbols were used for important natural elements and shown in Figure 1 is the symbol used for urine. As early as 400 BC Hippocrates noted the different odors and color of urine. About 1000 AD, Ismail of Jurjani recorded seven observations which could be made on urine for various interpretations. These were: quantity, consistency, color, odor, transparency, sediment, and froth.

Visual observations continued, and in the Middle Ages physicians were known as uroscopists and were nearly always painted peering into a container of urine – the urine glass that is seen in many engravings of the 13th to 15th centuries. This was a round-bottomed flask called a matula, and is depicted in Figure 2. Uroscopy later developed a poor reputation because charlatans, or uromancers, used the examination of urine not only to provide information about health and disease, but also as sort of a fortune-telling exercise to foretell the future. Such quacks were known as “Pisse Prophets”. A review of the role of urinalysis in the history of diagnostics medicine gives many more details of urine study before chemical analysis of urine was used.

2.2 Microscopic Examination of Urine Sediment

Of course, the visual examination of urine continues today with the microscopic examination of urine sediment. Chemical stains are often used to enhance the differentiation of the various elements formed. The addition of acetic acid to the sediment causes red cells to hemolyze and aids in their identification. Knowledge of the urine pH is also useful in the identification of sediment. Chemical tests are often used to identify various crystals in urine.

2.3 Chemical Tests

In the 1600s, Scribonius described the black urine in alcaptonuria, Frederick Dekker of Leyden detected protein in urine using heat and acetic acid, Herman Boerhaave measured the specific gravity of urine, and Thomas Willis tasted urine to detect the sweetness of urine caused by diabetes (and it was only a century later in 1776 that Matthew Dobson proved that the sweet taste was due to sugar).

In the 18th century, several chemical tests were developed specifically for use in urine studies. They included yeast fermentation for urine sugar, nitric acid precipitation of protein in urine, and the nitric acid colorimetric bilirubin test made popular by Leopold Gmelin. In 1841, Trommer introduced his test for sugar, which involved the reduction of blue cupric ions in hot alkaline solution; this test was later improved by Herman.
von Fehling. Perhaps the most widely known liquid test for urine sugar was described by Stanley Benedict in 1911, when he was a student at the University of Cincinnati. He not only devised Benedict’s qualitative solution for the estimation of urine sugar, but also developed a quantitative volumetric method in which the extent of copper reduction in a given volume of Benedict’s quantitative solution was carefully determined by titration while the solution was kept boiling over a Bunsen burner. Benedict made many contributions to analytical chemical methods during his career as Professor of Chemistry at Cornell University. Otto Folin of Harvard University Medical School was another famous biochemist who contributed to the early advances in clinical analytical chemistry, and Meites has written his biography. It is our belief that Victor C. Myers, who received his doctorate from Yale University in 1909, created the first real clinical laboratory with the extensive application of chemical measurements to blood and urine at the New York Postgraduate Hospital. This can be considered the beginning of 20th century urinalysis. In 1906, Dr Charles P. Emerson of Johns Hopkins University wrote the textbook Clinical Diagnosis, a significant part of which is devoted to urine study. For the first quarter of the 20th century, this text profoundly affected the importance of urine study as viewed by the medical profession.

2.4 Convenient Urine Tests

The idea of providing convenience to the clinical study of urine was first noted by Dr Walter Compton, who with Maurice Treneer (the chief chemist at Miles Laboratories in Elkhart, Indiana), devised a simple tablet containing cupric sulfate, sodium hydroxide, citric acid and a little carbonate. (After all, Miles was the maker of Alka-Seltzer, which also fizzed!) This test, Clinitest, is still widely used and when a tablet is dropped into a test tube containing urine, the heat of solution of the sodium hydroxide and the exothermic reaction of sodium hydroxide with citric acid supply enough heat to allow the sugar of the urine to reduce blue cupric ions to orange or red cuprous ions. Color blocks from blue through green to orange represent the amount of color change, and can be used to estimate the sugar concentration of the urine specimen tested. Essentially, this allows the copper reduction test to be performed without an external source of heat.

Our group, the Biochemistry Section of the Miles Ames Research Laboratory, continued to advance the convenience of urine testing by producing other single-use reagent tablets: Acetest for urine ketones and Ictotest, the ultrasensitive test for urine bilirubin. Both of these tests are still widely used today even after the introduction of the very convenient “dipstix” in 1956.

2.5 Dip-and-read Reagent Strip Tests

At the 1956 International Congress of Clinical Chemistry in New York, the first dip-and-read test was described by our group. This was Clinistix, a simple specific test for urine glucose. In the same year, Eli Lilly & Co., leaders in supplying insulin to those with diabetes, introduced Test-Tape® which is based on the same chemical principle. Glucose was, and still is, the most common urine analyte in the clinical laboratory. Urine protein is the second most common test, and the colorimetric test for protein was introduced in 1957. Since these two tests were performed on almost every urine specimen reaching the laboratory, it seemed logical to provide both tests on the same dip-and-read strip, and thus the first multiple reagent dip-and-read test was created, for glucose and protein. The next additions to the multiple reagent strip were tests for pH, occult blood and ketones. In 1969 the liver function tests for bilirubin and urobilinogen were added. In 1972 the nitrite test for urinary tract infections (UTIs) or bacteriuria was added. And in 1981 the colorimetric test for specific gravity finally came into being. In 1984 another indirect test for UTIs, a test for leukocyte esterase, was added as the final test of the ten-way multiple reagent strip. Each of these tests is a colorimetric test, and the reagent is matched to a series of color blocks of increasing intensity, proportional to the amount of analyte being determined. A color chart is shown in Figure 3.

2.6 Automation

In 1972, automation was introduced to the urinalysis laboratory with the large-volume laboratory instrument called Clinilab®. Reagent areas for each test were spaced on reels and fed through the sampler apparatus; the color intensity of the reacted reagent was measured by reflectance spectroscopy. Specific gravity was measured by the falling drop method, in which the time a drop of urine takes to travel between two marks, through a column of viscous fluid, is converted into specific gravity units. The Clinilab® was a “walk-away” instrument with automatic printout of results on a data tag attached to the urine specimen tube, so that no recording errors could occur. A semi-automated instrument, a “strip reader” called Clinitek®, was introduced for small-volume laboratories and physicians’ offices. This required the analyst to dip the reagent strip into the specimen and place the reacted strip on a tray table. Results were displayed on a lighted panel and copied by the analyst. Many improvements have been made over the years, and the latest version of the larger instrument is called the Clinitek® 500, while the smaller instrument is the Clinitek® 50. This latter instrument can also be used with the newest products, Clinitek® hCG, a test
for human chorionic gonadotropin (HCG), and Clinitek® Microalbumin, a test for microalbuminuria. A timeline adapted from a previous publication^8 and noting many of the important milestones in urine testing is shown in Table 1.

3 EVOLUTION OF URINE AND BLOOD TESTING USING DIABETES TESTS AS THE EXAMPLE

In ancient times, urine was poured on the ground to see if it attracted insects. The attraction of insects indicated an abnormality then known as ‘honey urine’ which was correlated with what later became known as diabetes. As mentioned in section 2.3, the method of “taste testing” was used by Dr Thomas Willis in the 1600s. Metal reduction tests that relied on the fact that glucose is a strong reducing agent to detect and quantitate its level in urine or blood were used in the early 1900s. Copper was the usual reagent but bismuth reduction was also utilized. The development of the convenient copper reduction test in tablet form was the culmination of the reduction tests. The biggest disadvantage of copper reduction tests was the fact that any reducing substance present in the urine specimen would react in the same way as glucose. This led to the use of the enzyme glucose oxidase to produce a test formulation specific for glucose. The same disadvantage of nonspecificity was also
true of blood glucose measurements, and the enzymatic reaction gradually replaced the reduction methods in the laboratory. The adoption of the convenient dip-and-read methodology for use on whole blood from finger punctures provided a convenient blood glucose analysis usable in any place, and at any time of the day or night. It thus allowed stricter control of blood glucose levels and provided a convenient alternative to trips to the doctor’s office or the hospital laboratory. To help standardize the reading of results of the colorimetric test, an easy-to-use reflectance spectrophotometer was devised to read the intensity of color formed in the chemical reaction. The most recent tests utilized in the control of diabetes are the tests for glycated protein and microalbuminuria. Glycated hemoglobin, or Hb A1c, is increased in persons with diabetes whose blood glucose is out of control for several days. It is a good monitor for checking the success of the therapeutic regime the diabetic patient is supposed to follow. The test for microalbuminuria is a predictive test. It has been shown that very small amounts of albumin excreted consistently by the kidney indicate that further deterioration of the kidney is likely to occur. Early detection of microalbuminuria allows steps to be taken to delay the onset of renal failure.

4 MOST COMMON URINE ANALYTES

Throughout this section, the chemical principles described are those commercially available under the series of Multistix® trademarks from Bayer Diagnostics. Similar products may be available under the Chemstrip® trademark from Roche Diagnostics, under the Rapignost® trademark from Behring Hoechst, and from KDK in Japan and others in the Far East.

4.1 Glucose

Glucose appears in the urine of a person whose pancreas does not produce active insulin to allow the body’s cells to metabolize glucose. Consequently the glucose level rises in the blood and when it becomes so high that the kidney tubules cannot reabsorb it all, it spills over into the urine. The specific test for glucose is a double sequential enzymatic reaction. The reagent contains glucose oxidase, peroxidase and a potassium iodide chromogen. Glucose oxidase reacts with glucose to form gluconic acid and hydrogen peroxide. In turn the peroxidase of the reagent reacts with the hydrogen peroxide to oxidize the chromogen to a colored compound. The intensity of color is proportional to the glucose concentration.

4.2 Ketones

Ketones are breakdown products of fat metabolism. When individuals cannot utilize carbohydrates to fuel their body cells, the cells use fat for fuel. The most common instance of fat metabolism is in diabetes where insulin is not available. However, in starvation or vomiting with no or little food metabolized, or in high fat diets, ketones may also appear in the urine. The ketones, acetone and acetoacetic acid react in strongly alkaline media with nitroprusside to form a purple color. The intensity of color is proportional to the concentration of ketones.

4.3 Protein

The principal protein appearing in the urine as a result of kidney dysfunction is albumin. This protein leaks from the serum through the damaged glomerular filter into the urine to signify renal disorder. Albumin is determined by using the principle of the protein error of indicators. Some acid–base indicators are subject to protein error; that is, they turn the color that indicates alkalinity in the presence of protein even if the pH is kept constant. In the protein reagent, the indicator tetrabromophenol blue is buffered strongly at an acid pH and is a yellowish color. Thus any blue color formed when the strip is dipped into a urine specimen is due to protein and not to a pH change. A highly buffered alkaline urine may occasionally overcome the strong acid to give a pH color change.

4.4 Occult Blood

Blood appears in the urine as a result of kidney disorder. The glomerular filter damage is great if cells can get into the urine. Red cells will hemolyze in a dilute urine
specimen or when they are damaged during the course of urine flow through the kidney. Hemolysis releases hemoglobin from the cell and it is the peroxidase-like activity of hemoglobin which is detected with this reagent. The reagent contains a solid peroxide and the chromogen 3,3',5,5'-tetramethylbenzidine. The reaction is similar to the second enzyme reaction of the glucose test. The peroxidase-like hemoglobin catalyzes the reaction of the peroxide to form the oxidized (blue) form of the chromogen.

4.5 Bilirubin

Bilirubin is the normal breakdown product of hemoglobin and it circulates in the bloodstream bound to the plasma albumin. Thus there is normally no bilirubin in the urine since albumin is too large a molecule to filter through the kidney. However, the liver conjugates bilirubin into the glucuronide, a soluble product excreted through the bile into the bloodstream and appears in the urine. If the liver and biliary system do not function properly, then bilirubin glucuronide backs up into the bloodstream and appears in the urine. The principal causes of bilirubinuria are biliary obstruction and hepatitis. In fact, detection of bilirubin in urine may be an early sign of hepatitis. The test is based on the coupling of bilirubin with diazotized dichloroaniline in the presence of strong acid to give a tan color. Bilirubin is light sensitive and it is essential that the urine be tested as soon as possible after excretion.

4.6 Urobilinogen

As noted in section 4.5, a small amount of urobilinogen is not excreted into the bile but circulates in the bloodstream. Therefore a small amount of urobilinogen is normally present in the urine. Urobilinogen is absent from the urine in cases of obstruction of the bile duct and is increased in other types of liver damage such as hepatitis, cirrhosis and in blood disorders such as hemolytic anemia where excess hemoglobin passes through the liver. Table 2 shows how testing for bilirubin and urobilinogen in urine can help provide a differential diagnosis of liver disease. The test is based on the Wallace and Diamond reaction; in strong acid, urobilinogen reacts with p-diethylaminobenzaldehyde to give a reddish-orange color, the intensity of which is proportional to the amount of urobilinogen present.

4.7 Nitrite

The test for nitrite in urine is an indirect chemical test for bacteriuria or UTIs. Most bacteria which cause kidney or bladder infections secrete the enzyme reductase which reduces nitrate to nitrite. There is nitrate present in urine because it is an end product of protein metabolism, but nitrite is never normally present in urine. Therefore if the test for nitrite is positive it always indicates the presence of significant numbers of bacteria—generally $10^5$ organisms per milliliter of urine. However, a few cases of UTIs are caused by bacteria which do not secrete reductase and therefore will not reduce nitrate to nitrite. Thus the nitrite test does not give a false positive result but in some cases does not react in the presence of bacterial infection. In this test, nitrite reacts with p-arsanilic acid to form a diazonium salt, which couples with 1,2,3,4-tetrahydrobenzo(h)-quinolin-3-ol to produce a pink color.

4.8 Leukocyte Esterase

Leukocytes or white blood cells are usually present in urine when there is an infection in the urinary tract because they are the cells which fight to destroy invading bacteria. Leukocytes release the enzyme leukocyte esterase into the urine and thus the test for leukocyte esterase is another indirect test for bacteriuria or UTIs. The chemical test for leukocyte esterase is based on the hydrolysis of the derivatized pyrrole amino acid ester to liberate 3-hydroxy-5-phenyl pyrrole. This pyrrole reacts in turn with a diazonium salt to produce a purple color.

4.9 pH

The normal urine pH ranges from 5 to almost 8. Urine pH varies in relation to the diet and the time of urine collection after eating, with acid urine excreted by individuals on high protein diets and alkaline urine excreted by those on diets high in vegetables and dairy products. Certain medications may cause typically acid or alkaline urines. The urine is likely to be acid in uncontrolled diabetes, and alkaline in UTIs. The reagent for the colorimetric determination of urine pH is a combination of methyl red and bromothymol blue. This gives a broad range of colors from orange at pH 5 through yellow and green to dark blue at pH 8.
4.10 Specific Gravity
The specific gravity (density) of urine varies with the amount of liquid ingested and excreted and is usually inversely related to the volume of urine. It is a measure of the amount of solids dissolved in the urine. Specific gravity values may be close to those of water (1.000) after intake of large amounts of liquid or in diseases such as diabetes or kidney disease. In contrast, in states close to dehydration from high salt ingestion, or excess perspiration, vomiting and diarrhea, the specific gravity may be as high as 1.300 or more. The unique colorimetric specific gravity test is based on the apparent change in $pK_a$ of the polyelectrolyte poly(methyl vinyl ether/maleic anhydride) in relation to ionic concentration. The indicator, bromothymol blue, is a deep blue-green color at low ionic concentration and changes to a yellow-green color at high ionic concentration. Ionic concentration of urine is directly related to specific gravity as determined by physical measurements.

4.11 Clinitek® Microalbumin
This is a reagent strip with two tests, one for creatinine and one for microalbumin. It is a useful test to identify the early stages of kidney damage, which is particularly important for patients with diabetes or hypertension. In order to allow the use of random specimens, the albumin-to-creatinine ratio is provided as milligrams albumin per gram or millimole creatinine. Albumin-to-creatinine ratios of 30–300 mg g⁻¹ creatinine indicate microalbuminuria. The test is read on the Clinitek® 50 (described in section 2.6). The creatinine reagent is based on the peroxidase-like activity of a copper creatinine complex, which catalyzes the reaction of diisopropyl-benzene dihydroperoxide with 3,3',5,5'-tetramethylbenzidine. The microalbumin reagent is based on dye binding using the buffered high affinity dye 3',3'-diido-4',4'-dihydroxy-5',5'-dinitrophenyl-3,4,5,6-tetrabromo-sulfonephthalein, with the resulting color ranging from orange to blue. Positive results from microalbuminuria testing are an indication of the likelihood of impending renal damage and proper intervention can delay serious kidney problems.

4.12 Human Chorionic Gonadotropin
HCG is the time-honored analyte which indicates pregnancy. The placenta produces this hormone soon after the fertilized egg is implanted in the uterus. The Clinitek® HCG reagent is based on an immunochemical reaction. The reagent strip is dipped into the urine specimen and the urine migrates through an area containing a monoclonal antibody specific for the beta subunit of HCG. Any HCG in the urine is bound to the antibody; the complex continues to migrate and is bound to a polyclonal antibody for the alpha subunit of HCG, which is immobilized on the strip. The instrument then displays or prints “negative” or “positive”; a positive result is obtained with HCG concentrations of 25 mIU mL⁻¹ or greater.

5 LESS COMMON URINE ANALYTES
There are literally hundreds of analytes in urine which in special circumstances can provide useful information. The fact that urine is an easy-to-obtain noninvasive specimen makes it the specimen of choice in many instances. Two of these groups of tests will be briefly discussed.

5.1 Inborn Errors of Metabolism
Several important analytes for which chemical analysis has been developed are in the excretory products caused by inborn errors of metabolism. Analytes appear in urine as a result of defects of various body systems. Most of them are best tested for on newborns since they may lead to mental retardation or other disabilities, and such consequences can be prevented in some instances if early detection is made. One inborn error was originally detected by testing urine for phenylpyruvic acid as a sign of phenylketonuria (PKU). This compound reacts with ferric ions to give a blue-gray or green-gray color. It is the product of faulty metabolism of the essential amino acid phenylalanine. If PKU is detected during the first several weeks of life, the infant can be placed on special protein hydrolysates with phenylalanine removed thus preventing the mental retardation which occurs in PKU. All infants in the USA are by law tested for PKU at birth, but blood phenylalanine assays are now used. Amino acid chromatography of urine is also used on infants suspected of having other amino acid abnormalities such as maple syrup urine disease, cystinuria or homocystinuria. Galactosemia is an inborn error in which galactose cannot be metabolized by the liver and is excreted in the urine. It is rare but testing is important since removal of lactose from the diet will prevent the mental retardation and early death seen in infants with this metabolic error. The screening test combination for galactose is a positive reducing test and a negative glucose oxidase test, with confirmation of galactose by more specific measurement.

5.2 Drugs of Abuse
Urine is the test substance of choice for detection of substances of abuse. Thin-layer chromatography (TLC) is often used. Several commercial products are available for testing for the metabolites of such drugs as morphine, cocaine, marijuana, amphetamines, and barbiturates.
The most widely used immunochemical test systems are EMIT® from Syva and Abuscreen® from Roche Diagnostics. Roche has recently introduced a rapid test called OnTrack TesTcup®.

6 OTHER BODILY FLUIDS

Most other bodily fluids used for chemical analysis are obtained by invasive techniques. And the most important, blood or serum, will be covered in other chapters of this encyclopedia. The following brief discussion summarizes bodily fluids other than urine.

6.1 Serum or Blood

There are many blood analytes of importance in health and disease. Presently most analyses are performed on serum rather than whole blood since analytes such as glucose are more stable if the red cells are removed and reagents can be reacted directly with serum while whole blood requires protein removal by precipitation and filtration. All tests are ordered from the clinical chemistry laboratory as single tests by physicians, and several may be grouped into panels pertaining to specific types of disease or particular possible sites of dysfunction, e.g. liver panel, cardiac panel. Tests range from easy-to-perform bedside analyses to those involving sophisticated complicated instrumentation that must be carried out in the main or specialized laboratory.

6.2 Sweat

The usual analyte of importance in sweat is sodium or chloride, as a presumptive test for cystic fibrosis. The most difficult part of the analysis is the collection of the specimen, since testing is usually performed on infants or small children.

6.3 Cerebrospinal Fluid

The important chemical analytes in cerebrospinal fluid (CSF) are total protein and glucose—especially in relation to meningitis, in which total protein is elevated beyond the normal 14–45 mg dL\(^{-1}\) while glucose is decreased from the normal level of 50–60% of the serum concentration. The enzymes lactate dehydrogenase and creatine kinase are also occasionally measured in CSF.

6.4 Amniotic Fluid

Specific chemical tests are performed on amniotic fluid in order to detect serious conditions in the fetus. Spectrophotometric readings for bilirubin/bilirubinoids are used to detect hemolytic disease of the newborn. Fetal lung maturity is determined by measurement of the lecithin–sphingomyelin ratio or by TLC determination of phosphatidylglycerol. Alpha fetal protein levels are measured to predict neural tube defects such as spina bifida.

6.5 Tears or Saliva

Tears and saliva have often been suggested as substitutes for serum, mainly to avoid the trauma associated with obtaining blood specimens. Diabetics who often collect fingertip blood specimens several times a day would particularly appreciate substitutes.

6.6 Stools

Although stools are technically not “other bodily fluids”, these specimens are grouped in this category in most clinical discussions and texts. An important analyte in stools is blood. Blood appears in the stool in the presence of colorectal cancer and is an easy, inexpensive cancer test. Blood can also appear in the stool as a result of bleeding stomach or duodenal ulcers or, in some cases, as a result of more benign causes such as bleeding gums. However, repeat tests after discussion with the patient can often clarify the source. Colorectal cancer detection must always be confirmed with physical tests such as colonoscopy or sigmoidoscopy.

6.7 Miscellaneous Bodily Fluids

A recent textbook\(^{(9)}\) describes the analysis of a variety of body fluids other than urine. It include several less often measured analytes, in addition to those mentioned here, as well as physical and microscopic analysis of seminal fluid; glucose and protein determinations in synovial fluid; and protein, various enzymes and pH in transudates and exudates of pleural, pericardial and peritoneal cavities.

7 WHERE WE ARE IN THE YEAR 2000

The chemical analysis of urine has attained an important role in the clinical laboratory, in the physician’s office and in home testing by the patient. We have emphasized the more common analyses performed on urine by professional chemists, medical technologists and technicians in laboratory settings. But there are millions of tests performed on urine specimens by individuals. Among the most common are pregnancy tests. These are based on the same chemical principles as those used for laboratory testing. Fertility testing, and urine glucose and ketone monitoring by diabetics are other home tests often used. In addition, tests for UTIs are performed by patients who have recurring infections, and
tests for glucose and protein are used by women during the course of their pregnancy as suggested by their obstetricians to detect problems early enough to avoid severe consequences.

Routine urinalysis provides a cost-effective, easy-to-do procedure on an easily collected clinical specimen, instantly yielding important information on the status of health or disease of an individual. Much discussion has been held on the pros and cons of widespread testing of urine performed on select population groups or on the general healthy population as a whole, such as in health fairs, yearly physical examinations, etc. It is our opinion that such chemical testing serves a unique and important function. Those who argue that the expense of testing is higher than the perceived benefit may justify, do not consider the positive value of a negative or normal result. Not only is the finding of positive reactions important, but the fact that the majority of those tested yield normal results is of just as much value to those individuals as is the detection of some abnormality.

8 THE FUTURE – INTO THE NEW MILLENNIUM

With the rapid explosion of chemical reagents and automated instrumentation which occurred with the evolution of the diagnostics industry, and with the significant attention to genetic diseases and gene manipulation of life forms, it is difficult to predict what will happen in the future. However, we feel confident that even when blood analyses can be performed without invasive specimen collection, chemical analyses on urine will provide important information that is not available by testing other clinical specimens.

We have long been proponents of the concept of testing for wellness. If there were easy-to-do tests to detect a variety of health problems, we could help those who were identified to delay or perhaps avoid major problems. For example, if there were a test for general cancer in the early stages, those showing a positive result could then be tested further with specific tests for specific kinds of cancer. Or a test for immunocompetence could be used to identify those with a low level of immunocompetence who could then be better protected against viral diseases such as human immunovirus or hepatitis.

It would seem that health care funds could better be spent to prevent disease rather than cure it once it has been established. And so our wish for the new millennium is that a way could be found to persuade individuals to become interested enough in maintaining responsibility for their own wellness that they change their lifestyle.

If everyone would embrace a healthy lifestyle and quit smoking, get optimal exercise, maintain a healthy weight, minimize fat intake, limit alcohol, and avoid or learn to cope with stress, there would be far fewer illnesses and enough funds to take care of those with unavoidable diseases.

Coatings Analysis: Introduction

Dennis G. Anderson
CK Witco Corporation, Dublin, USA

An organic coating is applied to a substrate for either or both of the following reasons: 1) to hide the surface over which the coating is applied (beautification) and/or 2) to protect the substrate from corrosion, degradation from the elements, etc. The types of organic coatings to be examined in the following chapters can be classified according to their end-use or method of application. Typical coating applications include the protection of architecture, automobiles, appliances, aerospace vehicles, aircraft, and food and beverage containers. Application mechanisms include brush, roll coating, coil coating and electrodeposition. Many excellent references are available for the characterization of coatings systems. Among the best is the “Fourteenth Edition of the Gardner-Sward Paint and Coating Testing Manual” published by the American Society for Testing and Materials (ASTM).[1] Numerous chapters deal with different characterization techniques and their application to specific coating types. Heavy emphasis is given to the use of tests published by the ASTM under the direction of Committee D-1. Due to their wide applicability, references cited in this introduction will also refer to ASTM methodology.

A typical organic coating contains three major ingredients. An organic and/or inorganic pigment provides decoration and hiding of the underlying substrate. The presence of an organic binder or resin provides a mechanism for adhering the pigment to the substrate and a solvent allows for viscosity adjustment to permit easy application. A fundamental characteristic of a coatings system, therefore, is the percentage of the total coating formulation which remains on the substrate following application. In general, this is a gravimetric determination whereby the solvent is allowed to evaporate under controlled conditions. A general nonvolatile procedure has been developed (ASTM D-2832), as well as methods to examine latex emulsions (ASTM D-4758), aerosols (ASTM D-5200), resins (ASTM D-1259), varnishes (ASTM D-4209) and specific procedures for the measurement of volatile organic content (VOC) (ASTM D-2369). Most of these methods involve heating in an oven at a given temperature for a fixed time; however, increased emphasis on the use of microwave heating has been noted recently. Inorganic pigment content is generally measured by heating a dried sample of the coating in a muffle furnace to remove organic binder species (ASTM D-3723). This technique is not generally useful with organic pigments due to their limited temperature stability. In this case, centrifugation techniques have been employed (ASTM D-2698 and ASTM D-2371). The determination of nonvolatile by volume poses a number of difficulties, which have been addressed in ASTM D-2697 and a newly developed procedure based on helium displacement (ASTM D-6093). Increased concern over the release of VOCs into the environment prompted the development of ASTM D-3960, which analytically defines this quantity as 100 – % nonvolatiles – % water or exempt solvent. Flash point is an important safety feature related to the use and transportation of coating materials. Among the methods currently in use are TAG open cup (ASTM D-1310), TAG closed cup (ASTM D-56), Setalash closed cup (ASTM D-3278), Setalash open cup (ASTM D-4206) and Cleveland open cup (ASTM D-92). Density and specific gravity measurements are common for coating finished products and raw materials. For liquids, hydrometers (ASTM D-2935 and D-1555), pycnometers (ASTM D-1475) and digital density meters (ASTM D-4052) are useful. For solids, it is necessary to differentiate between “apparent” and “true” density. The “apparent” density of a powder is measured following compaction by vibration, leaving air in the spaces between the individual powder particles. In “true” density, no air contribution is present during the density measurement (ASTM D-153).

In many cases it will be necessary to prepare cast films of coatings prior to physical or chemical property measurements. Measurement of appearance, for example, should be made using films prepared using the same application method expected to be employed during normal use of the product. For the measurement of physical properties, emphasis on the preparation of “defect free” films of appropriate film thickness is stressed. Typically, a coating is applied to a nonstick surface, such as: poly(ethylene), Teflon®, silicone coated paper or glass. Major concerns, in this regard, deal with proper wetting of the substrate by the coating and an ability to remove the film from the substrate without excessive force (ASTM D-823). Amalgamation off a tin foil surface has also been used (ASTM D-4708), but is no longer in general use due to hazards associated with the use of mercury. The simplest device for preparing a uniform cast film is the use of an aluminum or steel bar with a gap related to the film thickness desired. Excess paint is placed on the substrate and the bar is drawn across the substrate in a slow, uniform, motion. The use of automated devices is reported to produce more uniform films due to less variation in draw speed and downward force upon the bar (ASTM D-823). An alternate method for producing uniform cast films involves the use of a wirewound rod. Typically, the film applied using a wirewound rod is approximately one-tenth
the diameter of the wire on the rod. Once cast, wet film thickness can be measured using an Immont or Pfund wet film gauge (ASTM D-1212). Notch gauges, having notches of varying depth, have been used where thickness is estimated between highest notch which has been coated with paint and next highest uncoated notch. The estimation of dry film thickness on a nonferrous substrate makes use of eddy currents (ASTM D-1400), whereas the same measurement on a ferrous substrate uses the magnetic properties of film and substrate (ASTM D-1186). Measurement of free film thickness is required if mechanical film properties are to be measured. In this case, microscopic techniques and a number of micrometers and dial gauges (ASTM D-1005) are generally adequate. For mechanical film property measurements, specimens of known cross-sectional area and length are prepared. As these specimens are stretched, force and elongation are continuously recorded. From this data, tensile strength, elongation at break and tensile modulus at a given elongation can be calculated. A critical physical property for floor coatings is coefficient of friction. In one method, the force required to pull a weighted sled across the surface is measured (ASTM D-1894 and ASTM C-1028), while in a second approach a platform containing a sled is slowly raised until the angle is sufficiently steep to cause the coated panel to begin sliding down the incline (ASTM-4518). In a third case, the traction of footwear on painted surfaces is measured using a variable incidence tester (ASTM D-2370). The flexibility of coatings on metallic substrates is measured by bending around a series of cylindrical mandrels 0.125 to 1.00 inches in diameter. Bending around successively smaller diameter mandrels takes place until the coating cracks. An alternate procedure makes use of a conical mandrel (ASTM D-522), where the coated sample is bent around a metal cone (1.5° dia. to 0.125° dia.). The diameter at which cracking occurs is taken as the point of failure. With some types of coatings, only solvent evaporation occurs during the drying process and the dried film continues to be sensitive to solvent. In other cases, chemical reactions occur following solvent removal and the solvent resistance of the finish improves as curing is complete. The resistance of dried coating films to solvent (ASTM D-5402), therefore, can be a convenient way to measure the extent of cure. Another useful measure of cure includes the use of a series of pencils of varying hardness (ASTM D-3363). The softest pencil required to scratch through the film is the hardness of the coating. Knoop hardness utilizes the indentation of a pyramidal diamond indenter (ASTM D-1474) and Sward rocker hardness (ASTM D-2134) measures the swings of a pendulum after rocking a given degree from an equilibrium position. Resistance of a coating to forward and reverse impact is also a measure of cure (ASTM D-2794). A coated panel is placed under a spherical weight dropped from a variety of heights. The number of “inch pounds” of force required to cause coating failure is used as a measure of cure. Tape adhesion (ASTM D-3359) continues as a measure of adhesion. The paint film is crosshatched down to the substrate using a sharp blade. Pressure sensitive adhesive tape is then applied to the crosshatched area. When the tape is removed, the percentage of the coating removed by the tape is used as a measure of coating adhesion. Balanced beam scrape adhesion (ASTM D-2197) uses a balanced beam to which a platform with load weights and a rod holding a scraping loop at a 45° angle are attached. The load on the scraping loop is increased to a point where the coating is barely removed from the substrate. Differential scanning calorimetry, thermomechanical analysis and dynamic mechanical analysis are also useful in measuring cure, since the glass transition temperature of a material increases as cure increases. Any exothermic or endothermic processes occurring during the curing process are also readily examined in this manner. Evaporative rate analysis measures the evaporation of a 14C labeled solvent from the surface of a coating. The greater the degree of cure, the smaller the degree of penetration of solvent into the film and the more rapid the evaporation rate. Abrasion resistance is a major performance parameter in certain applications. The use of rotating, weighted, abrasive wheels is very popular (ASTM D-4060), as is the use of falling sand (ASTM D-968) and gravel (ASTM D-3170).

One of the initial stages in coating production is dispersion of the pigments. This process involves breaking down any pigment agglomerates into the ultimate particle size formed during manufacture. The extent to which dispersion has been achieved is generally monitored using a Hegman fineness of grind gauge (ASTM D-1210). A metal bar with a calibrated, tapered, slot 0–4 mm in depth is generally used. An excess of sample is placed at the deep end of the channel and the excess dispersion is drawn to the shallow end of the channel using a scraper. The presence of large particles is observed at some point along the slot when the film in the slot becomes broken. Similar information is obtained by casting a film of the pigment dispersion onto a sealed paper chart using a doctor blade. In this case, the sensitivity of the test is dependent upon the gap of the doctor blade and visual ability to observe oversized particles. Instrumental methods for the examination of average particle size and particle size distribution include the use of a disc centrifuge, low angle laser light scattering (LALLS), a Coulter® counter, sieves (ASTM E-11) and optical microscopy (ASTM E-20). The viscosity and rheological properties of coatings have a very marked effect on application characteristics and ease of use. In measuring viscosity, it is necessary to differentiate between several shear related phenomena.
If the viscosity of a material is independent of shear rate, the material exhibits Newtonian behavior. If viscosity increases as shear rate increases, the material is dilatent, while a material that decreases in viscosity with shear rate is deemed thixotropic. It is desirable, for example, for an architectural coating to be somewhat thixotropic. The coating should be viscous when in the can, such that insertion of a brush picks up a useable amount of paint. Once shear is applied, when brushing begins, we want the coating to lose viscosity, so that a thin uniform layer can be applied. The rheological properties desired for a given coating type will generally be dictated by the application mechanism to be applied during use. Many instruments are used to measure viscosity. Among the most common are the Stormer rotating paddle (ASTM D-562), a circulating spindle (ASTM D-2196) and a cone and plate (ASTM D-4287). A desire to measure the shear dependence of viscosity has also led to the development of numerous variable shear rate viscometers. Timed flow through an orifice is a convenient measurement technique for lower viscosity materials. Typical configurations involve the use of a Ford cup (ASTM D-1200), or a Zahn “dip type” cup (ASTM D-4212). The time necessary for an air bubble to rise in a glass tube of known dimensions is the basis for the Gardner–Holdt technique (ASTM D-1545). This procedure is relatively simple, but lacks fine definition between materials of similar viscosity. Since viscosity is quite temperature dependent, extremely good temperature control is required for accurate measurements. Several other practical methods have also been developed to meet specific application needs. These include a thixotropic index test (ASTM D-2196), a leveling test (ASTM D-4062), a procedure to measure brush drag (ASTM D-4958) and a sag resistance test (ASTM D-4400).

When light enters a paint film, some is scattered, some is absorbed and some bounces off the substrate and comes back out of the film. The smaller the fraction of light that emerges from the coating film, the greater the ability of the coating to hide any imperfections, etc. in the substrate. The minimum film thickness required to provide for a given degree of light bouncing off the substrate and back to the surface is called the “hiding power” of a coating system. The thinner the film required, the more efficient the coating, since more area can be effectively covered by a given volume of paint. The simplest way to measure hiding power is to cast a film of an experimental coating and a control material on a sealed paper chart having white and black sections and visually comparing how effectively the substrate features are hidden. For a more quantitative measure, the ratio of reflectance over a dark and light substrate is measured photometrically. This is deemed the “contrast ratio” for a given film thickness and permits the calculation of $ft^2 \text{gal}^{-1}$ the coating can cover at a given degree of hiding. Another useful property related to substrate masking is the change in hiding which occurs upon solvent evaporation (ASTM D-5007). The gloss of a coating is its ability to reflect incident light from the air-coating interface. Specular gloss is the ratio of incident energy flux to reflected energy flux as measured at angles such as 20 and 60° from the perpendicular (ASTM D-523). Sheen, on the other hand, is measured at 85° from the perpendicular (ASTM E-284), a much more grazing angle than specular reflectance.

A number of atmospheric factors influence the weathering of coatings. These include sunlight intensity and wavelength distribution (spectrum), temperature, humidity and rainfall amount, type and amount of pollutants present and the presence of fungus, mildew, mold and insect attack. By far the most reliable testing of weathering involves the exposure of coated panels to a variety of atmospheric conditions for varying lengths of time. This process, while providing extremely useful data, is very expensive and time-consuming. To speed up this process, a number of artificial weathering mechanisms have been employed. ASTM D-5894 utilizes cyclic corrosion/UV exposure by cycling a salt fog/dry cabinet and a fluorescent UV/condensation cabinet. Supplements to this procedure include fluorescent/UV condensation and water exposure (ASTM D-4587) and recommended guidelines for the operation of this apparatus (ASTM G-53). The use of a carbon arc increases the intensity of ultraviolet light considerably (ASTM D-822, ASTM D-5031 and ASTM G-23) as does the use of a xenon arc (ASTM G-26). Application of water (ASTM D-1735, ASTM D-4585 and ASTM D-2247) or salt fog (ASTM B-117 and ASTM G-85) also increase severity of corrosion and coating degradation. Other measures of chemical resistance include the evaluation of rusting phenomena (ASTM D-610 and ASTM D-1654), blistering (ASTM D-710) and resistance to household chemicals, such as water, ethanol, acid, base, soaps and detergents, condiments, grease, oil, fats and beverages (ASTM D-1308). Electrochemical impedance measurements are also growing in popularity relative to evaluating the corrosion resistance properties of a wide variety of coating systems.

The previous sections of this introduction have concentrated on the characterization of formulated coatings systems. To obtain more complete compositional information, the remaining contributions to the encyclopedia must be consulted. Classical analysis provides functional group information as well as the measurement of volatile, pigment and binder content. Infrared and Raman spectroscopy completes qualitative analysis for organic and inorganic functional groups. Organic species can be further characterized via nuclear magnetic resonance spectroscopy. Volatile components are most conveniently analyzed...
COATINGS

examined using gas chromatography. Nonvolatile species can also be examined in some cases following derivitization, thermal or chemical degradation. Thermal analysis provides useful data concerning decomposition mechanisms and thermal stability. Elemental analysis for trace and major components is possible using atomic spectroscopy. Mechanical property measurements yield valuable information on cured coatings systems, where rheology and viscometry are uniquely suited to the examination of uncured coating application properties. Finally, microscopy and related techniques give the coatings analyst powerful tools to study coating defects, problems with exterior durability and substrate interactions.

REFERENCES

In atomic spectroscopy, vaporized neutral atoms are detected by measuring either the absorption or emission of light at characteristic frequencies. In atomic absorption (AA) spectroscopy, radiation is absorbed by the atom in the process of exciting an electron from a lower energy state into a higher energy state. In atomic emission (AE) and inductively coupled plasma (ICP) spectroscopy, radiation is released when an electron from an excited energy state relaxes into a lower energy state. The energy required for these transitions occurs in either the visible or ultraviolet region of the electromagnetic spectrum.

Atomic spectroscopy is a very useful technique in the field of coating analysis. It is primarily used for the analysis of metallic constituents, such as certain pigments and coating additives. It is extremely sensitive, and can detect several dozen different elements. It is especially useful in determining whether or not a particular coating contains environmentally hazardous levels of heavy metals, such as lead, cadmium, and chromium. Disadvantages of the technique include its inability to determine the chemical form in which the element is present, somewhat laborious sample preparation procedures, and the inability to determine other important constituents of coatings, such as resins and solvents.

1 INTRODUCTION

Coatings are complex materials, which contain pigments, plasticizers, additives, solvents, and one or more polymeric materials. Therefore, a thorough analysis of a coating requires the use of several analytical techniques. One technique which is useful for the analysis of metallic constituents such as certain pigments and additives is atomic spectroscopy.

There are several variations of atomic spectroscopy utilized in the coatings industry, including AA, AE, and ICP spectroscopy. This chapter will briefly address the theory of these techniques, followed by examples of their use in the field of coatings analysis.

2 ELECTROMAGNETIC RADIATION

A detailed discussion of the theory of electromagnetic radiation and of atomic spectroscopy is contained elsewhere in this work. Therefore, only a brief introduction is contained here.

2.1 Theory of Electromagnetic Radiation

The light by which we see the world around us is a form of electromagnetic radiation which, in its simplest terms, is energy traveling through space. In a vacuum, the velocity of electromagnetic radiation is equal to the speed of light \( c = 2.99 \times 10^{10} \text{ cm s}^{-1} \). The classical interpretation of this radiation describes it as a series of waves propagating through space with a certain wavelength (\( \lambda \)) and frequency (\( \nu \)). This simple wave-like interpretation was able to explain certain macroscopically observed phenomena, such as diffraction, but was found to be insufficient to explain other phenomena, such as the photoelectric effect.

The photoelectric effect, whereby light impinging on a photoelectric cell results in the generation of current, was more readily explained by the quantum mechanical interpretation of electromagnetic radiation. Quantum mechanics describes electromagnetic radiation as small discrete particles of energy referred to as photons.

In either case, electromagnetic radiation can be described by the simple relationship that \( \lambda = V/\nu \). In other words, the wavelength of the radiation (the distance...
between two successive maxima or minima of the wave front) is equal to the velocity of the wave front divided by its frequency in cycles per second, or hertz. Because, in a vacuum, the velocity is equal to the speed of light, the equation can also be stated as $\lambda = c/\nu$.

The quantum mechanical, or particle-like interpretation of electromagnetic radiation relates the energy of a photon with its frequency, according to the equation $E = \hbar \nu$, where $\hbar$ is Planck's constant ($6.624 \times 10^{-34}$ erg s), and $\nu$ is again the frequency in cycles per second, or hertz.

As this simple equation illustrates, the energy of electromagnetic radiation is directly proportional to its frequency. Therefore, it is reasonable to expect that light of varying frequencies can interact differently with matter. This is indeed true and accounts for the wide variety of spectroscopic techniques in use today. Frequencies ranging from about 20,000 to $10^{14}$ cm$^{-1}$ encompass the visible and ultraviolet region of the spectrum, and involve relatively high-energy processes such as outer electron transitions. These transitions form the basis of atomic spectroscopy.

2.2 Theory of Absorption and Emission Processes

Of AA, AE, and ICP spectroscopy, the one most widely used in the coatings industry is AA spectroscopy.

The electrons in an atom occupy certain energy levels about the nucleus. The electronic configuration is such that the greatest population of atoms resides in the lowest energy state, or ground state. If the atom is exposed to light of an energy exactly matching the difference in energy between a ground state orbital and a higher energy orbital, a portion of this light can be absorbed and the electron will be raised, or excited, from the ground state to a higher energy excited state. Thus, if a suitable light source is coupled with a detector capable of sensing the attenuation of this light source as a portion of it is absorbed by the atoms in its path, the concentration of a particular species can be determined. This is the basis of AA spectroscopy.

It seems reasonable that if an electron in an atom is excited to a higher energy level by the absorption of electromagnetic radiation, it will eventually decay back to the initial ground state. When it does, a photon of light equal in energy (frequency) to that initially absorbed will be generated. The detection and quantification of this emitted radiation is the basis of AE spectroscopy.

3 ATOMIC ABSORPTION AND ATOMIC EMISSION SPECTROSCOPY – EQUIPMENT

Detailed descriptions of the processes and equipment involved in absorption and emission spectroscopy can be found elsewhere in this text. However, this section contains a brief description of the three major components of an AA/AE spectrometer: burners and atomizers, spectrophotometers, and sources.

3.1 Burners and Atomizers

The atomic processes which are responsible for the basis of AA/AE spectroscopy occur in the flame. Therefore, it is appropriate to begin a discussion by considering burners and atomizers.

The purpose of an atomizer is to produce a fine uniform spray of the solution containing the sample. This fine suspension is carried into the reaction zone of the flame by the gas stream used to support combustion, usually air or oxygen. In order to reduce noise and increase precision, the atomizer must be able to deliver this solution at a steady rate, and the temperature of the flame should be relatively constant. Therefore, precisely controlled flow rates of both the fuel and the oxidant are essential.

Most spectrometers employ what are referred to as premix burners. In a premix burner, the aspirated sample, fuel, and oxidant are mixed prior to reaching the burner opening. This opening consists of a long narrow strip, and the flame produced is smooth, nonturbulent, and quiet. Most premix burners are designed with a series of baffles which are located before the burner head and which promote mixing and allow larger droplets to be drained off. Indeed, the majority of the sample aspirated into a premix burner actually goes down the drain, contributing to a loss of sensitivity. However, the advantages of such an aspirator usually outweigh the disadvantage of sample loss.

Several complicated events occur once the sample actually reaches the flame. These include the evaporation of the water or other solvent carrying the sample, the decomposition of the vaporized analyte to produce neutral atoms or radicals, and the excitation of a certain percentage of these individual atoms.

Since it requires considerable energy to vaporize and dissociate inorganic salts, the temperature of the flame is one of its key parameters. The most common type of flame is the air–acetylene flame, which can maintain a temperature of approximately 2200°C. The other common flame is the nitrous oxide–acetylene flame, which reaches a temperature of approximately 2900°C.

Not only do hotter flames more effectively vaporize and decompose samples, but they can also reduce the number of chemical interferences. The primary source of chemical interference is compound formation within the flame, which can result in broad band absorption and emission. As the flame temperature is increased, many of these compounds are decomposed into atoms, thus reducing or eliminating the problem. Hot flames...
are also desirable in AE spectroscopy, where their higher energy results in the excitation of an increased number of elements. However, if too high a temperature is used, it is possible that a significant portion of the neutral atoms may become ionized, and therefore useless analytically.

It should be pointed out that nonflame atomizers exist for AA equipment. By far, the most common type of nonflame atomizer is the graphite furnace. A typical graphite furnace consists of a hollow graphite cylinder a few centimeters in length, and a few millimeters in cross-section. The tube is heated electrically to produce very high temperatures. The sample is usually introduced via a micropipet through a hole in the top of the tube.

The heating of the graphite tube is usually accomplished in stages. The first stage is a low-temperature step used to volatilize any water or solvent in the sample. The second higher temperature step is used to ash the sample, followed by a rapid increase to temperatures of 2000–3000 °C resulting in atomization of the elements.

The main advantage of the graphite furnace is improved detection limits. In a graphite furnace, there is no loss of sample down a drain tube and the actual residence time of the element in the analytical zone is greatly increased.

### 3.2 Spectrophotometer

The best burner/flame assembly would be of little use without an efficient monochromator to sample the analytical line of interest accurately. Both single beam and double beam monochrometers are available. Most instruments are of the single beam type, which use a rotating chopper. This allows the source radiation to pass alternately through the flame or to be sampled unattenuated.

In a double beam instrument, the source radiation is split into two beams, one of which passes through the flame, while the second, or reference beam, is detoured around the flame by a series of mirrors. The two beams are then recombed after the flame, and the ratio between the sample beam and the reference beam are electronically measured.

### 3.3 Sources

By far, the most common source used in AA spectroscopy is the hollow cathode lamp. The hollow cathode lamp consists of a cathode manufactured from the element of interest, situated adjacent to an anode in an enclosed glass tube which has a glass or quartz window. An inert gas, such as neon or argon, at a few millimeters of pressure, is used as a filler gas inside the tube. A potential difference across the anode and cathode results in the sputtering of a small number of metal atoms from the cathode, which in turn collide with the inert gas, resulting in the production of radiation. Although most lamps use cathodes manufactured from a single element, it is possible to purchase multielement lamps which contain from two to perhaps six different elements.

As of yet, no broad band continuous sources have been found suitable for AA spectroscopy. This is a severe limitation, because it means that the technique is quantitative, not qualitative. In order to analyze for a particular element, a hollow cathode lamp manufactured from that element must be mounted in the instrument. ICP spectrometers, which will be discussed later in this chapter, are a means of solving this problem.

### 4 SOURCES OF ERROR

Although the absorption and emission lines used in flame photometry are much narrower than those encountered in many other spectroscopic techniques, there are still several sources of error to be considered. Common sources of error include background effects, ionization effects, and spectral and chemical interferences.

With the possible exception of fluorescence techniques, almost any analytical measurement has a background signal associated with it. In AA and AE spectroscopy, the two main sources of background signal are the flame itself and matrix effects, with matrix effects usually predominating. In emission spectroscopy, these effects can usually be accounted for by slowly scanning over the region of interest and drawing in a base line, either manually or electronically. This is not possible, however, in AA spectroscopy, using monochromatic line sources such as hollow cathode lamps.

Instrument manufacturers have devised several techniques for greatly reducing errors due to background radiation. These techniques are discussed in greater detail in other sections of this encyclopedia.

While it may be debatable whether or not ionization is actually a source of interference, it can certainly affect detection limits. Both absorption and emission spectroscopy rely on the population of neutral metal atoms in the flame. In absorption spectroscopy, the concentration is determined by measuring the attenuation of the source beam, which is being absorbed by the ground state atoms. In emission spectroscopy, the concentration is determined by measuring the intensity of radiation emitted when atoms which have been thermally elevated to an excited state subsequently decay and emit radiation. In both processes, a reduction in the population of neutral atoms results in a decreased signal. One mechanism whereby this population is decreased is ionization.

The ionization process occurs when a neutral metal atom absorbs sufficient energy to eject an electron, thus
forming an ion. This process will be more prevalent at higher flame temperatures. However, selecting a relatively low temperature flame may not be the best alternative, because it may result in greater spectral and chemical interferences.

For many metal atoms, the ionization potential is much higher than the energy available from the flame, and ionization is not a problem. However, for easily ionizable elements such as potassium, the percentage ionization can be well over 50% in some of the hotter flames. One way to reduce this effect is the use of a radiation buffer or ionization suppressant. An ionization suppressant is simply another easily ionized element, an excess of which is added to the sample. In essence, the use of an ionization suppressant causes a large increase in the density, or concentration, of electrons in the flame, and thus suppresses the ionization of the element of interest as a result of the Le Chatelier effect.

Spectral interferences are caused by the overlapping of lines or bands from an impurity at or near the wavelength of the analyte. A common example of spectral interference is the effect of calcium on the determination of sodium. The characteristic yellow line of sodium, at 590 nm, overlaps a band produced by calcium hydroxide, which is a thermally stable compound that can exist in the flame. This type of interference can be minimized by using a high-resolution monochromator.

Spectral interference is usually more of a problem in AE spectroscopy than in AA spectroscopy. In absorption spectroscopy, the source line produced by the hollow cathode lamp is extremely narrow and would therefore not be appreciably absorbed by other species whose absorption bands are close to the element of interest. However, there are still examples of spectral interference even in AA spectroscopy. For example, iron and platinum both have absorption lines at 2719 Å. If this type of interference is suspected, it may be possible to perform the analysis using a line other than the main absorption line.

Chemical interferences are caused by the element of interest forming a thermally stable compound in the flame, thus decreasing the population of free metal atoms. For example, some elements can form stable oxides or hydroxides within a flame, such as calcium. One of the best ways of reducing chemical interference is to use a flame of higher temperature, although ionization effects must be considered.

Another source of interference is instability in the flame itself. This is usually not a problem with modern instrumentation, which can produce very consistent flow rates. However, particulate matter in the sample can result in flame fluctuations which can affect the accuracy and sensitivity of the analytical measurement.

5 INDUCTIVELY COUPLED PLASMA SPECTROSCOPY

Both the theory and instrumentation of ICP spectroscopy are covered in detail elsewhere in this publication. Therefore, the current chapter provides only a brief outline of this field.

5.1 Theory

ICP spectroscopy is closely related in theory to the more conventional AE spectroscopy discussed previously. In essence, the technique relies on the measurement of the intensity of light emitted when excited state atoms relax to their ground state. Instead of using a flame to accomplish this, ICP uses a plasma. The plasma is formed as a result of argon gas being excited by an inductively coupled radiofrequency generator. The plasma is formed in what is referred to as the plasma torch, into which the sample is carried by a separate stream of argon gas. Temperatures in the plasma are much hotter than any conventional flame, and can reach 7000 °C. As a consequence, several elements can be analyzed by ICP spectroscopy which could not be analyzed by AE spectroscopy.

An advantage of ICP spectroscopy, which it shares with AE spectroscopy, is the fact that individual hollow cathode lamps are not required. Therefore, when coupled with an appropriate monochrometer, ICP is a very efficient technique for conducting simultaneous multielement analysis. Indeed, it would rarely be used to analyze for a single element, as the cost of both the instrumentation and the analysis would be prohibitive.

Earlier in this chapter, it was stated that one of the disadvantages of very hot flames was the increased ionization of the sample, resulting in poorer detection limits. This is not the case, however, in ICP spectroscopy because of the suppression effect caused by the very large number of argon ions present in the plasma. In general, detection limits are an order of magnitude better than AA spectroscopy, and calibration curves also span a wider linear range.

5.2 Inductively Coupled Plasma Instrumentation

Briefly, there are two fundamental types of ICP instrument on the market, distinguished by the type of monochromator employed, the sequential or simultaneous.

In most sequential spectrometers, the light emitted when excited state atoms relax to the ground state is dispersed by a movable diffraction grating and subsequently focused on a fixed detector. Another design is to keep the grating in a fixed position and move the detector. Although modern monochrometers can perform this function in a relatively short time, the technique is still
sequential, since the radiation emitted from a specific element must first be collected before the grating or detector is moved to determine the next element in sequence. Current instruments can do approximately 20–50 elemental determinations per minute. This is dramatically faster than a conventional AA instrument.

In simultaneous spectrometers, a bank of detectors, typically photomultiplier tubes, diode arrays, or some type of charge-coupled device, are positioned at fixed points about the grating so that light at several preselected frequencies can be measured simultaneously. Therefore, the analysis is truly simultaneous: multiple elements can be detected and quantified virtually instantly.

While simultaneous spectrometers would appear to have a significant advantage over sequential instruments, not only are they typically more expensive, but they lack the flexibility of a sequential instrument. Because only a limited number of detectors can be used, only a limited number of preselected analytical lines can be measured. Most instruments can be set up to detect approximately 30–40 elements. However, this deficiency has been mitigated by the introduction of a segmented array charge coupled device as a detector. One such device is claimed by its manufacturer to be able to measure 60 elements in less than a minute at multiple wavelengths.

6 APPLICATIONS

Approximately 70 elements can be detected by atomic spectroscopy. Detection limits vary, but are typically on the order of approximately 1 part per million or less. Typically, paint samples are digested in hot acid, sometimes after a preliminary ashing step in a muffle furnace to remove resins and polymers. Although several hours may be required for sample preparation, the actual analysis time is extremely short. Samples are generally introduced in a dissolved state. Many of the methods have been devised to address environmental health and safety issues relating to heavy metals such as lead, cadmium, and chromium.

The following are brief outlines of many of the published test methods for analyzing coatings or coating-related materials by atomic spectroscopy, and Table 1 summarizes the methods in terms of analytes and conditions. Many of them are published annually by the American Society for Testing and Materials (ASTM). Another excellent source for published test methods is the journal Analytical Chemistry. Since 1987, this journal has published its Application Reviews in the June 15th edition of every odd-numbered year. Prior to 1987, they were published in the April editions. For example, the 1993 review lists 13 AA/ICP methods for the analysis of coatings.

ASTM D 3335 is a method for determining low concentrations of lead, cadmium, and cobalt in paint by AA spectroscopy. For samples containing approximately 500 parts per million lead, the specimen size is approximately 2–3 g of liquid coating, or 1–2 g of dried paint film. Smaller quantities can be used for samples containing higher amounts of lead.

Liquid specimens are first dried on a hot plate or in a low-temperature oven, after which time they are treated the same as dried specimens, and subjected to an ashing procedure in a 500 °C muffle furnace. After ashing, the residue is digested in 10 mL of 1 : 1 nitric acid on a hot plate and filtered through medium porosity filter paper into a 50-mL volumetric flask. The container and filter paper are washed with small quantities of hot ammonium acetate solution, and the volume finally adjusted to 50 mL with deionized water. The diluted solution is aspirated

into an AA spectrometer, which has first been calibrated with lead, cadmium, or cobalt standards.

Another method for determining lead in liquid paint is ASTM D 4834. The first step in this procedure is to prepare three standard paints by accurately weighing a compatible lead compound to a paint which has already been shown to contain less than 10 parts per million of lead. The standards are prepared such that they contain approximately 300, 600, and 900 parts per million lead based on their nonvolatile content.

Samples and standards are analyzed by accurately weighing approximately 0.5 g of liquid specimen into a 10-mL volumetric flask. The flask is then diluted to the mark with methyl isobutyl ketone (MIBK) for solvent-reducible coatings, or water for water-reducible coatings. The standards and specimens are then aspirated immediately after mixing, and their absorption recorded. The amount of lead can then be determined and related to the coating’s nonvolatile content once this has been determined in accordance with other appropriate ASTM methods. It is important that MIBK or water is aspirated immediately after each standard or specimen, to prevent the fouling of the aspirator/nebulizer system.

Another method for determining the lead content of dried paint samples is the Association of Official Analytical Chemists (now known as AOAC international) Method 974.02. In this procedure, a few tenths of a gram of either liquid or solid paint is weighed into 16 × 150-mm test tubes, and digested in approximately 5 mL of concentrated nitric acid using a heating block or sand bath. The temperature is brought to 90–100 °C until the initial fuming has subsided, and then increased such that the vapors are condensing in the top 1–2 cm of the test tube. The digestion is continued for 3 h, after which time the specimens are cooled, transferred to 25-mL volumetric flasks, and rinsed with several small portions of deionized water. The specimens are diluted to volume, and then allowed to settle for at least one-half hour. Any floating residue may be removed by aspiration through a disposable pipet prior to introduction into the spectrophotometer.

A method for determining both lead and chromium in air particulate filter samples by AA spectroscopy is described in ASTM D 4358. The procedure covers the analysis of pigment dust on filters, expressing the results as micrograms of lead or chromium. The method does not address sampling procedures, only the analytical procedure. Briefly, the filter media is digested in 6 mL of one part concentrated nitric acid diluted with three parts water for approximately 10 min on a hot plate. Addition of 2 mL of 50% ammonium acetate solution follows, along with water as needed, with continued heating for 1 h. The samples are then cooled, transferred to a 10-mL volumetric flask, diluted, and analyzed by AA.

ASTM D 3718 describes a test method for determining low concentrations of chromium in paint by AA spectroscopy. Calibration of the instrument is performed by using chromium working solutions of various concentrations, which bracket the expected chromium concentration of the sample to be tested. The standards are made from a 100 part per million working solution prepared by dissolving potassium chromate in water. This working solution is first adjusted by adding an oxidizing solution (potassium permanganate in sulfuric acid), followed by dropwise addition of a reducing solution (hydroxylamine hydrochloride in water) until the permanganate color has just been discharged.

Once the calibration curve has been constructed, samples are analyzed by weighing approximately 5 g of liquid coating or 3 g of dried coating into porcelain crucibles. For liquid coatings, the crucibles are heated on a hot plate or in a low-temperature drying oven to remove solvents. The specimens are then heated further on the hot plate until the material chars, at which time the crucibles are ashed in a muffle furnace at 500 °C for 1–2 h. The percentage ash is determined. After grinding to a uniform powder, 0.02–0.2 g of ash is then weighed directly into polytetrafluoroethylene (PTFE) decomposition vessel inserts along with 10 mL of oxidizing solution. The digestion vessels are then placed in a 105 °C oven for 1.5 h, removed, and allowed to cool. The contents are then quantitatively filtered directly into 50- or 100-mL volumetric flasks. The filter paper is then washed several times with small volumes of water, and hydroxylamine hydrochloride solution added dropwise to the filtrate until the permanganate color has been discharged. Finally, the volumetric flasks are diluted to the mark with water and analyzed by AA spectroscopy.

ASTM D 3717 describes a method for determining low concentrations of antimony in paint by AA spectroscopy. Standards are made using suitable aliquots of 0.1 mg mL⁻¹ standard antimony solution, to which 40 mL of concentrated HCl and 8 drops of a stannous chloride solution have been added. Specimens consist of 5–10 g of liquid coating or 2–6 g of dried coating. The liquid specimens are first dried on a hot plate, and are then treated the same as dried specimens. The temperature of the hot plate is increased until the material chars, after which time the specimens are ashed in a 500 °C muffle furnace for 1–2 h. They are allowed to cool, and then 40 mL of concentrated hydrochloric acid and 8 drops of stannous chloride solution are added. Condensers are added and the flasks refluxed for 1 h.

The digested specimen is filtered into a 100-mL volumetric flask. After rinsing and washing, the flask is diluted to the mark, and the specimens aspirated into an AA spectrometer.
ASTM D 3624\(^2\) describes a method for determining low concentrations of mercury in paint by a cold vapor AA technique. The apparatus is calibrated using various size aliquots of a working mercury standard containing 1000-ppm mercury. These aliquots are added to a series of 250-mL gas washing bottles. Enough water is added to each bottle to make a total volume of 100 mL and then 5 mL of sulfuric acid and 3 mL of nitric acid are added. Dropwise additions are made of 0.1 N potassium permanganate solution to each bottle until a pink color persists, and then 1 mL of hydroxylamine hydrochloride solution is added until the pink color is discharged. The bottles are then sealed using fritted glass inlet tubes and stoppers, and nitrogen is allowed to flow through the bottles.

The apparatus is constructed such that the nitrogen flows from the specimen bottle into a water vapor trap and a drying tube, and finally into a suitable absorption cell positioned in the spectrometer compartment. This is a cell 100 mm in length having quartz windows, aligned within the spectrometer compartment to provide maximum transmittance. A calibration curve is constructed using the mercury standards and then the various specimens are analyzed.

The sample preparation for ASTM D 3624 involves weighing liquid paint or dried specimens into PTFE inserts of acid decomposition vessels. The inserts are then placed in an oven at 60°C for 1 h to remove all volatiles. Sulfuric acid and nitric acid are then added to the decomposition vessel inserts, and the vessels are sealed and placed in a 140°C oven for 1.5 h. After cooling, 5 mL of cold water are added, and the contents are diluted and filtered into a 100-mL volumetric flask. The residue and filter paper are washed several times with small volumes of water, and the flask filled to the mark with deionized water. The samples are then treated in the same fashion as the calibration standards.

ASTM method D 4563\(^2\) describes a method for determining the titanium dioxide content of pigments by AA spectroscopy. The initial step is to isolate the pigment from the liquid paint by drying at 110°C followed by ashing at 450°C. The percentage pigment must also be determined by first drying and subsequently ashing a known weight of liquid sample. A portion of the pigment thus obtained is dried for 2 h at 105°C. The dried specimens are then transferred to 500-mL flasks, to which 8 g of ammonium sulfate and 50 mL of concentrated sulfuric acid are added, along with five drops of concentrated nitric acid. This mixture is heated on a hot plate until solution is complete (usually not more than 5 min of boiling), cooled, and diluted with 100 mL of water.

The contents of the flasks are then transferred to 1000-mL plastic volumetric flasks, and 50 mL of hydrochloric acid and 30 mL of hydrofluoric acid are added. After cooling, the flasks are diluted to the mark with water, and the solutions are then filtered prior to being analyzed by AA spectroscopy using a nitrous oxide–acetylene flame. The standard for the test procedure is a different sample of pigment which has previously been analyzed in accordance with ASTM D 1394.

Surfactants are widely used as additives in various types of paints. Chattaraj and Das\(^4\) have described an indirect AA spectroscopy method for the determination of cationic surfactants. The method involves diluting the sample with water, and extracting 1–4 mL of it in a 100-mL separatory funnel with 2 mL of a sodium hexanitrocobaltate(III) solution, 10 mL of a sodium phosphate/citric acid pH 7 buffer, and 5 mL of 1,2-dichloroethane. The conditions favor the formation of an ion pair between the cationic surfactant and the hexanitrocobaltate(III) anion, which is soluble in the 1,2-dichloroethane. Successive extracts are obtained, combined, and diluted to 10 mL. The cobalt concentration in the organic phase is then determined via graphite furnace atomic absorption spectroscopy (GFAAS), using the 240.7 nm line of a cobalt hollow cathode lamp.

A discussion of the methods used for the AA determination of barium, cadmium, zinc, and phosphorous in vinyl stabilizers was presented by Nagourney and Madan.\(^5\) Vinyl stabilizers are combinations of metal salts and various organic additives which are used to inhibit color formation and increase the effective service life of polyvinyl chloride materials. The authors discussed several extraction methods, including aqueous extraction using a variety of acids, and organic extractions using appropriate solvents. Analysis of the final extracts was performed by AA spectroscopy, GFAAS, and ICP/AE spectroscopy.

Alkyl tin compounds are widely used as additives in paints designed for ship hulls to prevent biological growth. Katsura et al.\(^6\) have described the sensitivity enhancement by organopalladium complexes of the GFAAS determination of such compounds leached from ship paints.

GFAAS is usually a very sensitive technique. However, the technique is not as sensitive as might be expected for tin in organotin compounds because of their volatile nature. This volatility results in significant evaporation of the analyte from the graphite boat prior to the actual analytical measurement. Katsur et al. evaluated several chemical modifiers in an attempt to improve the sensitivity of the technique, and found that PdCl\(_2\)(CH\(_3\)CN)\(_2\) dissolved in ethyl acetate/hexane enhanced the detection limit of organotin materials by a factor of approximately 19. The authors then conducted a study to evaluate the efficacy of this modifier in determining the amount of total tin leached from ship paints by artificial seawater.

A half circular specimen painted with a coating containing tributyl tin chloride was rotated in 1.5 L of
artificial seawater at 60 rpm. Seawater in 5-mL aliquots was taken after various time intervals, and placed in 100-mL separatory funnels. Hydrochloric acid and saturated sodium chloride solution were added, and the mixture was diluted with 50 mL of water. Ethylacetate–hexane (10 mL) was then added, and the funnels were shaken vigorously and allowed to sit in such a way that the aqueous layer separated. This extraction procedure was repeated three times and all the organic layers were collected and concentrated to less than 4 mL. A 1-mL volume of PdCl$_2$(CH$_3$CN)$_2$ and ethyl acetate–hexane was added, and the total volume of the sample was diluted to 5.0 mL with additional ethyl acetate–hexane. A 10-mL quantity was then injected into the graphite furnace and analyzed for tin using the 246 nm line.

Paudyn and Smith\(^7\) described the determination of various elements in paints by ICP/AE spectroscopy using microwave-assisted digestion. Approximately 15–20 mg of powdered paint samples were transferred into Teflon\(^8\) microwave digestion vessels. Liquid paints were also evaluated, after first evaporating any solvents present by leaving the vessels uncovered in the microwave oven for 1 min. Nitric acid and hydrofluoric acid were then added to the vessels, which were then capped, weighed, and heated in the microwave oven for 35 min. After washing into PTFE beakers the specimens were reduced to approximately 1 mL on a hot plate, and finally diluted to 50 mL with deionized water.

The diluted specimens were then analyzed on an ICP spectrometer against multielement working standards. Elements reported on included lead, barium, zinc, calcium, titanium, sulfur, magnesium, aluminum, copper, antimony, and manganese.

Rademeyer and Fischer\(^8\) reported a method to determine metals in wax. The method uses a V groove nebulizer and a heated spray chamber to nebulize molten waxes directly into an ICP spectrometer. Calibration of the technique was done via the method of standard additions by mixing a multi-element standard oil with melted wax. Detection limits of 0.3–0.9 mg g\(^{-1}\) were reported for iron, copper, cadmium, and vanadium. However, problems were encountered with precision as the result of nebulizer instability, and the authors offered suggested courses of action.

This work describes the analysis of coating materials using gas chromatography (GC). An element of volatility is necessary for samples to be amenable to the technique and early applications concerned the analysis of solvents and their mixtures. The examination of low molecular weight and volatile components of coatings followed; these included trace or residual products in resins. The resinous or binder components are essentially nonvolatile, and to be amenable to GC a considerable reduction in molecular weight is necessary. This has been achieved by chemical cleavage of condensation systems, with examination of the reconstituted reactants or their derivatives, or by thermal means in the absence of oxygen where pyrolysis provides fragments which may be related to the initial composition. Chemical cleavage was applied to alkyd resins, acrylics, polysiloxanes, polyurethanes and polyethers during the 1960s and while the results were most satisfactory, the time required was considered excessive. Several decades later, some of the problems have been eliminated but the procedures have found little application. Pyrolysis was also introduced at the same time and while the early reports were of low reproducibility, refinements in technique allow reproducible results to be achieved rapidly. The major area of the application of GC to coating materials is pyrolysis, where, in combination with mass spectroscopy (MS), valuable information is achieved in minutes.

Other coating applications of GC include inverse chromatography which has found negligible use and headspace chromatography which is widely used in determining the source of odors or taints in coated food packaging. Special applications of GC include use in forensic science where accelerants used by arsonists are readily detected and also examination and identification of paint flakes by pyrolysis GC/MS. Similarly pyrolysis techniques are used in conservation studies, with the analysis of old paints on art works.

1 INTRODUCTION

GC was employed early in coating analysis and the applications have continued to increase. GC is now probably the most widely used analytical tool of the coatings manufacturer. The technique was reported...
in 1952, followed by reports on solvent analysis, in 1956, based on a presentation at an early international conference, in 1957, and in 1958 together with reports on monomeric plasticizers, drying oils, and other general works.\(^1\)

While the analysis of coatings, including the use of GC, has been regularly reviewed since 1961,\(^2\) few comprehensive works have appeared, although a monograph was published in 1974.\(^3\) This work detailed packed column separation and tentative identification methods which were applicable at the time but have now been largely replaced by capillary column separation and spectroscopic detection. The development of GC in the analysis of coatings is best considered by study of the regular reviews.\(^2\)

Spectroscopic, particularly infrared, spectroscopy and MS, and chromatographic techniques including GC, liquid chromatography and size exclusion chromatography, are the principal techniques used in coating analysis. The approximate molecular weight range applicable to these three major chromatographic techniques is shown in Figure 1.

For GC, the sample must possess some element of volatility. The efficiency of separation may be improved by modification of the compound studied. Many compounds contain highly polar groups and frequently exhibit poor chromatographic behavior, although by alteration of the chemical nature of the compound, the chromatography is usually improved. Derivative formation generally employs acetylation or esterification. The formation of a simple or trimethylsilyl derivative of an alcohol or acid increases the molecular weight of the compound but greatly reduces the polarity and increases the volatility. When polymers are used as coating binders, a considerable reduction in molecular weight, typically by several orders of magnitude, is necessary to provide fragments amenable to GC.

This reduction is achieved with condensation systems by chemical degradation with examination of the reconstituted reactants or their derivatives, or by thermal means, where, in the absence of oxygen, pyrolysis occurs, providing fragments which may be related to the initial composition. Chromatography is a separation method in which the components of a sample partition between two phases, one of the phases, the stationary phase, is a bed with a large surface area, the second phase is the mobile phase which in GC is a gas. The sample is vaporized and carried by the mobile phase or carrier gas through the column. Based on solubility, each component partitions between the two phases. The distribution constant is the major factor in the partitioning equilibrium and is the ratio of the concentration of a compound in the stationary phase to the concentration of the compound in the gas phase. The greater the solubility of the compound in the stationary phase, the greater the distribution constant and the greater the retention or slower the elution.

This factor, formerly described as the solvent efficiency, and the column efficiency determine the resolution of chromatographic peaks. The column efficiency is concerned with the peak broadening as a sample moves along the column. The usual measure of column efficiency is the plate number, which is readily determined from a chromatogram but which varies for different types of compounds. Packed columns possess 500–2000 plates per meter, while typically a capillary column may exhibit 2000–4000 plates per meter. While a packed column may be 2 m in length, a capillary column may be 60 m in length, the total number of plates present being almost two orders of magnitude higher and the resolution accordingly very much greater.

Early reports of coating analysis tended to focus on stationary phase selectivity but the greater use of capillary columns has focused on thermally stable phases of modest polar character. These phases have found considerable use and have superseded many of the specialist selective phases which were of low thermal stability and of very limited application.

The most commonly used detector is the flame ionization detector, with the limits of detection being approximately 10–11 g L\(^{-1}\), this being about two orders of magnitude greater than the thermal conductivity detectors. These have increased greatly in sensitivity and the unstable thermistors once used have disappeared. The other general detector used is the mass spectrometer, with detection limits of approximately 10–12 g L\(^{-1}\); widespread acceptance has been achieved. The amount of sample required for analysis is minuscule; readily identifiable mass spectra are obtained with 40–60 pg of material. A variety of specific detectors, i.e. electron capture detectors and nitrogen–phosphorus detectors,

2 SOLVENT ANALYSIS

The analysis of solvent mixtures was traditionally carried out by examination using chemical and physical testing of fractions obtained by fractionation. The initial report of Whitham\(^4\) supplemented these methods with GC. Even the low resolution of packed columns made fractionation unnecessary, and very small amounts of sample were required for analysis. Elution depended on the stationary phase used, so that with a nonpolar phase such as dimethyl polysiloxane, elution followed a boiling point sequence, while with polar phases specific interactions occurred and elution of low boiling species could be retarded. Highly selective stationary phases allowed difficult separations to be readily made. Separation of the isomeric xylenes was reported in 1964 using a chemically treated bentonite clay. The boiling points of the isomers of xylene are \(144\,^{\circ}\text{C, } 139\,^{\circ}\text{C and } 138\,^{\circ}\text{C, the isomers boiling at } 138\,^{\circ}\text{C and } 139\,^{\circ}\text{C being superimposed.}\) With this similarity the isomers are eluted as two peaks on normal nonpolar and polar columns. When using a capillary column, unsatisfactory resolution occurs on a nonpolar column, but if the stationary phase has modest polarity three component peaks are resolved to the baseline.

When using packed columns, aliphatic and aromatic hydrocarbons, which are both groups of compounds of low polarity, are eluted in approximate boiling point sequence on low polarity stationary phases and are greatly intermingled. During the 1960s it was found that highly polar stationary phases including \(N,N'-\text{bis(2-cyanoethyl)}formamide (CEF) retarded the elution of aliphatic hydrocarbons, and the application to solvent mixtures\(^5\) showed that the \(C_{12}\) aliphatic hydrocarbon, \(n\)-tridecane (bp \(234\,^{\circ}\text{C), was eluted well before benzene (bp } 61\,^{\circ}\text{C). While these stationary phases were of value in the petroleum industry, they were of limited use with coating solvents because CEF has a low maximum-use temperature and the determinations were made at \(115\,^{\circ}\text{C which is inadequate for the resolution of many hydrocarbon fractions. Separations of solvent mixtures have been carried out since the late 1970s using capillary columns with modest to polar stationary phases. The thickness of the coating layer of stationary phase is of importance; the thicker the film the greater the retention of the solvents. A film thickness of \(0.25\,\mu\text{m is frequently used. If analysis is restricted to packed column operation, the peak overlap that frequently occurs can be minimized by conducting the analysis on several columns of different polar character or by the use of differences made by extraction with water, sodium chloride solution and sulfuric acid of varying strength.\)

Where the solvent mixture is free of resins and pigments, direct injection is obvious, but very often the solvents are present in liquid coatings and the treatment must be modified. Traditionally, steam distillation or dry distillation, often in the presence of added inert material, was carried out. With the widespread use of water-soluble or partly water-soluble solvents, steam distillation is of little value, similarly neither is dry distillation because of the minor degradation of resins and organic pigments before complete solvent removal is achieved and these materials produce disproportionately large spurious peaks. With packed and capillary columns, direct injection of coating has been practised, with nonvolatile material retained in inert injection liner packing. Direct injection of paint is not recommended, as the hot injector bakes paint in the syringe needle.

The solvents are conveniently removed from the coating prior to analysis. A technique and device which has been found effective is shown in Figure 2. The small device is based on the work of Haslam, Jeffs and Willis.\(^6\) A sample of coating (0.1–0.5 g) is injected into the bulb using a coarse syringe, ensuring that the opening is not contaminated. The sample is frozen in liquid nitrogen and the opening sealed. After evacuation, the opening above the v-shaped receiver is sealed. The device is removed from the coolant and the receiver is cooled. The sample is placed in boiling water and the solvents are distilled off, condensing in the receiver. If the coating contains 30% solvent, 0.1 g of coating will produce hundreds of microliters of solvent for examination. A small amount of coating provides a generous amount of solvent for examination. When a coating is air-dried simply by

![Figure 2 Apparatus for semimicrodistillation of solvent from a liquid coating.](image-url)
evaporation or is cross-linked by a chemical reaction, the film initially contains solvent which is gradually lost and over time reduced by diffusion. The residual solvent in a film is readily determined by GC in association with low temperature pyrolysis. A filament pyrolyzer at temperatures 300–500 °C, or a Curie point pyrolyzer with a low-temperature element, may be employed, because little degradation of the constituent resin occurs at these temperatures. Alternatively the solvent may be determined by headspace GC.

3 MONOMERS

Like solvents, monomers form a significant part of coatings: the polymers formed providing the basis of many resins. Monomers like solvents are generally very volatile and are thus readily amenable to GC, which is a readily applied quality control tool. Both packed and capillary chromatography are used with a wide variety of stationary phases and column temperatures. Many monomers are extremely volatile and have low boiling points, so that the column temperatures required are low, often less than 100 °C. Analyses of these monomers are frequently directed towards the determination of small amounts of related materials, often polymerizable but with different reactivities, or nonpolymerizable or odorous which occur in different monomer deliveries, so that the resolution and consequently the column used are dependent on these factors. Other analyses concern residual monomer determination. Most resins have an indication of the specified maximum levels of residual monomer that they contain, i.e. frequently 0.1%, and determinations of headspace monomer content can be readily carried out. A sample of the resin or formulated coating is either heated in a sealed jar and a large sample (i.e. gas) injected into the chromatograph, or the sample is examined in a commercial headspace analyzer and gas chromatograph. In producing a counter or copy of a commercial material, headspace analysis will normally show what monomers have been used in the manufacture of the resin and valuable preliminary information can be obtained before pyrolysis. With both these latter applications, considerable resolution is required and a capillary column is indicated. When injecting a large gas sample, an appropriate split ratio is needed if a mass spectroscopic detector is used.

4 PLASTICIZERS

While monomeric plasticizers must be of low volatility to be effective, they are readily determined by GC. Packed column chromatography has allowed homologous aliphatic (i.e. succinates, adipates, suberates) and aromatic (i.e. phthalates) and phosphate plasticizers to be resolved. The use of capillary columns allows greater resolution, although these are frequently not required, as short packed columns rapidly allow determination of the plasticizer in a coating. High temperatures for separation are frequently unnecessary; many separations being carried out at 200–250 °C.

Many plasticizers, particularly ester types, are manufactured by esterification procedures and as it is not practical to carry the reaction to completion, it is necessary to remove residual alcohols, which give the product an unacceptable odor before sale. The alcohols are frequently mixtures of isomers which are of different reactivities and possess different odors. Separation of the components and any half esters may be effected on a long packed column (4–5 m, 1/8") or more effectively on a capillary column. The analysis may be hastened using a wide bore (0.53 mm) capillary column. The separation of the low and high molecular weight species may be optimized using a multistep temperature regime. The alcohols may be resolved by an isothermal or temperature programmed operation, after which the temperature is rapidly increased in order to separate the esters isothermally or by temperature programming.

5 VEGETABLE OILS

The first report on GC concerned fatty acids and their esters, and since that time thousands of papers have appeared concerning these materials. Vegetable oils are readily amenable to GC and the complete oil may be examined as glycerides of molecular weight approximately 800, or much more commonly and successfully as esters, usually methyl esters. The oils or glycerides are subjected to hydrolysis or less frequently transesterification. A multitude of esterification procedures have been reported and include reaction with methanol or higher alcohols in the presence of various catalysts, reaction with trimethylsilyl reagents or reaction with diazomethane. Use of the latter material has the advantage that the only product, apart from the methyl group, is nitrogen. Care must be exercised when using diazomethane because a number of accidents have been reported.

The unsaturated nature of vegetable oils is not normally lost during either esterification or GC, which may be carried out using either a packed or capillary column with either nonpolar stationary phases or more suitably with polar columns. The temperature of examination is usually within the range 200–250 °C. Early studies considered the examination of polymerized or partly polymerized
vegetable oils. These results were unsatisfactory and have continued to be unsatisfactory. Once the unsaturation has been lost by autoxidative polymerization, it cannot be restored. Early studies where the viscosity of vegetable oils was increased by heating have shown that the constituent oil may be readily determined by analysis of the un polymerized portion. While such oils are now of no importance, partial and minor polymerization occurs during alkyd manufacture but the constituent oils are readily identified. Where a high degree of autoxidative polymerization has occurred, the constituent oils may be determined by gas chromatographic examination of the degradative fragments obtained after oxidative cleavage, as was frequently carried out more than half a century ago.

6 FISH OILS

These triglyceride oils are significant in countries that have a significant fishing industry and are used in coatings in the same manner as vegetable oils. Fish oils, as produced, contain large amounts of saturated oils, but these are largely removed before sale. Most vegetable oils are largely C18 fatty acids with up to three double bonds. Fish oils contain significant amounts of C20, C22, C24 and small amounts of C26 fatty acids and up to six double bonds.

Analysis follows the procedures for vegetable oils; the differences in fatty-acid chain length and unsaturation readily allow identification.

7 TALL OIL

Tall oil is a by-product of the Kraft Process for producing wood pulp from pine wood. Unlike other oils, the material exists as fatty acids and consists of approximately equal parts of long chain fatty acids and rosin acids. Where the Kraft process is carried out, use of tall oil in coatings occurs. Analysis as esters follows the procedures for vegetable oils; only a slightly higher temperature is required to elute the rosin esters.

8 AEROSOL COATINGS

Aerosol coatings form a lucrative niche market. The coatings are generally of a fairly basic type packed by contract aerosol fillers for the coating manufacturers and largely sold to householders. Much attention has been applied to developing containers which do not block easily and prevent efficient application. With aerosols, two types of GC analyses are possible, both for the propellant and for the coating. In the simplest case the aerosol container may be refrigerated and the contents discharged into a chilled container, providing in effect a headspace atmosphere. More suitably, the container is frozen, pierced and placed in a sealed pressure vessel fitted with an injection port. The propellant, which is either a hydrocarbon, a halogenated hydrocarbon or an inert gas, thaws first and is analyzed using a gas sampling syringe. The analysis generally detects some of the solvent but this does not present any problem. By weighing the intact container and the container on thawing, the percentage propellant is determined within a few percent. The thawed coating is transferred to a sealed container and analyses conducted as for a liquid coating.

9 COATING ADDITIVES

Many additive materials are used in coatings, usually in small concentrations, to introduce or contribute to a special property. Effective control of these additives is necessary and GC where applicable is ideal, although many of the materials are polymeric or single compounds of high molecular weight. The materials should usually be separated from the coating prior to analysis, and techniques include liquid extraction or supercritical fluid extraction.

Materials which are considered to be of low thermal stability may often be determined and include inhibitors such as hydroquinone, catechol and resorcinol. Similarly promoters used in reactive polyester resins, such as N,N'-dialkylanilines which may be estimated directly and cobalt salts which require hydrolysis and estimation as methyl esters, may be determined. Driers are metal soaps and after hydrolysis, the methyl esters or, in some cases, the free acids, are examined.

Many coatings contain ultraviolet absorbers and several dozen of these may be estimated directly. Tin compounds are also used and these require conversion into derivatives. Tin compounds are also used as toxins in coatings and similar analytical techniques are applied. Antioxidants have been traditionally used with natural rubber and later with synthetic rubbers, and have found some acceptance with vinyl and polyolefins. Many antioxidants have been identified by GC.

Preservatives may often be subjected to direct chromatography, but in a film or on a substrate can be detected by low-temperature pyrolysis, the temperature being such that minimal degradation of the resin occurs while the more volatile components are expelled. Limitations to the use of such techniques are that before all the additive is liberated, significant pyrolysis of the resin has occurred.
10 GENERAL METHODS OF RESIN ANALYSIS

All of the materials mentioned so far have been of relatively low molecular weight and suitable for direct chromatographic examination or after simple derivative formation. The major component of a coating film is the resin, which is of high molecular weight and low volatility. To be suitable for examination considerable reduction in the molecular weight is necessary. This is achieved by degradation which may be of two types, namely thermal degradation or pyrolysis and chemical degradation. Pyrolysis is applicable to resins in general, because if sufficient thermal energy is applied then the various constituent bonds are broken. Among the strongest bonds are the C–C bond and the C–H bond, and the latter is stronger; the former is often broken. Unfortunately, rupture is random and a wide range of products is frequently produced. In condensation polymers the main polymer chain is not made up of C–C bonds but is composed of functional groups which may be cleaved by chemical means. With a few materials direct chromatography is possible; these are low molecular weight materials that are monofunctional and react into the final polymer. Epoxy diluents used to reduce the viscosity of epoxy products are identified by GC. Other related analyses are for the detection of impurities in resin-making ingredients such as trace materials in bisphenol A and for phenols, amines and halogenated materials.

Pyrolysis finds much greater application than chemical degradation and has the advantage that analysis is rapid, requiring effectively only the time required for the components to pass through the column, and the technique is applicable to all resin samples. The major disadvantage is that a multitude of components are produced and the results are usually not quantitative. Chemical degradation suffers from the disadvantages that it is only applicable to condensation polymers and the time required is much greater than for pyrolysis. The advantages are that a complete analysis, rather than an analysis of reaction products amenable to GC, is obtained and the results are normally quantitative. Pyrolysis initially required a much smaller sample than chemical degradation, but currently little difference in sample size for the two techniques is required. A recent modification of pyrolysis is the technique widely known as pyrolytic methylation developed by Challinor and renamed thermally assisted hydrolysis and methylation. A small sample of resin or coating film, typically 5 µg, is mixed with 5 µL of tetramethyl or tetrabutylammonium hydroxide, and subjected to Curie point pyrolysis at 770 °C. The results are qualitative – partial esters and ethers of the degradation products being formed.

10.1 Pyrolysis

Early studies utilized pyrolysis external to the chromatograph, but, currently, in situ pyrolysis with pyrolyzers attached or built into the chromatograph are universally used. Two basic types of pyrolyzer are available namely: (1) the continuous mode- or furnace-type where the resin sample is introduced into a heated microfurnace attached to the injection port of the gas chromatograph with the volatile pyrolysis products being rapidly swept into the column by the carrier gas and (2) the pulse mode-type where the resin is attached to the pyrolysis element which is rapidly heated to a predetermined temperature with the volatile pyrolysis products being swept into the chromatograph column. The pyrolysis element may either be a filament or ribbon of noble-metal alloy heated resistively or a ferromagnetic wire heated to its Curie point inductively. A range of ferromagnetic wires are available, with Curie points of 358 °C for a nickel wire to 980 °C for an alloy wire consisting of 50:50 iron and cobalt. Details of some commercially available ferromagnetic wires are shown in Table 1.

The requirements for pyrolysis GC to produce reliable and reproducible results were not known when the technique first attracted attention in the 1960s. Relatively large samples were used, not intimately in contact with the pyrolysis element and often with slowly increasing temperatures. It is now recognized that small samples, typically 2–5 mg, are desirable, although forensic casework has been conducted with 1 µg samples. The temperature of the sample should rapidly be increased and heat transfer should be maximized.

The temperature of pyrolysis is important and partly depends on the nature of the polymer. Polymers of high thermal stability or those heavily cross-linked require a higher temperature than does a simple thermoplastic. The bond strengths of the constituent atoms and the association of these bonds influences both the ease and type of degradation. In pyrolysis, stable free-radicals

are usually formed and the fragments are stabilized by rearrangement. Temperatures of 500–600 °C are regarded as minima, although lower temperatures, like those that use the lowest Curie point wire (i.e. 358 °C) are widely used to liberate loosely held additives or residues. An excessively high temperature is not recommended as increased amounts of low molecular weight compounds and gases are formed. It is not helpful to identify these products as they are often typical of organic compounds in general, being often formed by secondary reactions, rather than products of a particular polymer. Pyrolysis temperatures of 700–800 °C are suitable.

Pyrolysis GC of polymers has been the subject of several thousand reports and has been detailed in a number of monographs, and in many reviews. Two recent reviews respectively detail almost 600 representative references to polymer pyrolysis, the majority being of polymers applicable to coatings, and almost 500 references concerning coatings materials.

### 10.2 Chemical Degradation

Chemical cleavage has been applied for decades and was used with various polymers before the development of GC. The best known example is alkyd resins, materials whose analysis was revolutionized by the use of chromatographic detection. Other early uses of chromatographic detection after chemical cleavage, normally hydrolysis, were the hydrolysis of polyurethanes, the determination of methoxy groups in cellulose, the degradation of polyethers and the acidic hydrolysis of polysiloxanes and linear polyamides. The microanalytical Zeisel reaction, where all alkoxyl groups were determined as methoxy groups, was transformed by the use of GC such that each individual alkoxyl group is determined as the appropriate alkyl halide. The technique was first applied to acrylic copolymers and later to copolymers with other esters.

Prechromatographic reaction GC was extensively developed by the American chemist, Siggia, in 1972. A microreactor was built from an old pyrolyzer and connected to the injection point of a gas chromatograph. Many students were employed in testing many types of compound including some classes of polymers.

A 1–10 mg sample was mixed with a prefused fusion reagent consisting of potassium hydroxide containing approximately 15% water, approximating the hemihydrate, with sodium acetate (1–10%) as a flux. The alkali was present as a substantial excess, i.e. 30–50 : 1, the fusion temperature was 250–350 °C and the reaction period 0.5–1.0 h. Reaction products amenable to GC were rapidly determined but high molecular weight reaction products and the half of the compound that was converted into potassium soaps remained in the reactor or were gradually carried into the column. All the alkali metal hydroxides have been used to achieve cleavage. The melting points of the common hydroxides are shown in Table 2. In addition to possessing a desirable melting point, potassium hydroxide melts have a greater solubility for organic compounds and the viscosity is lower.

External fusion using the same fusion reagent and comparable reaction conditions has been carried out with many polymer materials. The sample used has varied in size, initially being 100 mg, but with developments in reactors a sample size of 2 mg is adequate. The advantages of external fusion are that the reaction products of the hydrolysis may be worked up and materials present as metal salts are converted into volatile compounds that are readily chromatographed. In this way complete analysis of the resin is possible. In addition the reaction products have been subjected to other chromatographic techniques, i.e. gel permeation chromatography and high-pressure liquid chromatography.

A recently described microfusion reactor is shown in Figure 3 and consists of two parts, namely the reactor shell and the flange. The reactor shell is a square stainless-steel block containing a cylindrical cavity 23 mm deep and 20 mm in diameter. The flange has an orifice (1-mm diameter) in the center which allows entry to the cavity and combines with the main reactor cavity of the shell. The orifice is sealed with a cap fitted with a heat-resistant silicone rubber septum. A thin stainless-steel gasket seals the cover and the reactor shell. The cover is fitted to the reactor shell by four screws.

Degradation of condensation polymers has also been reported using acidic reagents, where cleavage of both ester links occurs in addition to cleavage of other groups, the reactions having been reported individually and simultaneously. Most organic and mineral acids as shown in Table 3 have been used, but often with the formation of undesirable by-products. A reagent that has been used successfully is a mixed anhydride of p-toluenesulfonic acid and acetic anhydride. Other monoprotic acids have been used with highly cross-linked or thermally stable polymer systems and include trifluoroacetic acid and trifluoroacetic anhydride.

The chemical degradation of polymers has been described in several reviews.\(^{17,18,20,21}\)

### 10.3 Pyrolytic Methylation

The coinjection of a free carboxylic acid and tetramethylammonium hydroxide was reported in 1979 and the technique was extended by Challinor a decade later.\(^{9}\)

The technique as described previously has been directed towards coating materials for forensic purposes. It has been postulated that the mechanism of the procedure concerning reaction of the polymer when intimately mixed with tetramethylammonium hydroxide and heated above 400 °C is hydrolysis, forming salts which undergo thermal fragmentation to the methyl derivatives.

The extent of application of pyrolytic methylation has been included in a review.\(^{21}\)

### 11 CONDENSATION SYSTEMS

Condensation systems were developed earlier than addition systems—such systems in many applications having now been largely displaced. The majority of coating resins and many other specialty polymers remain as condensation systems.

#### 11.1 Alkyd and Polyester Resins

These resins have remained the backbone of the coating industry for more than 50 years, and remain as the major tonnage film former despite the general acceptance of water-based systems for architectural finishing. The chemical analysis of alkyd resins dates from the
1930s and appeared as a standard specification\(^{22}\) in 1940. The first step, hydrolysis, was retained, and gravimetric detection of the reactants was replaced by GC, with estimation of polyols and acids as acetates and methyl esters, respectively. Packed columns were first used, but separations were restricted. The three dimethyl phthalate isomers were resolved as two peaks on a non-polar column, with the ortho-ester being well resolved while the iso-esters and tere-isomers were superimposed, while on a polar polyester column two peaks result, but the tere-ester appears as a single identity. The three isomers have been separated by temperature programming on a cyanopropylpolysiloxane\(^{23}\) packed column, but are readily separated by isothermal operation on a dimethylpolysiloxane capillary column. A wide variety of other acids are used in alkyd and polyester resins. The linear or vegetable oil free resins contain homologous aliphatic dicarboxylic acids, and while homologs are not well resolved by infrared spectroscopy, good separation is achieved using GC. Many resins contain small amounts of maleic or fumaric acids, and while it is not possible to decide which acid was initially present because thermal isomerization occurs, analysis is readily achieved. Fiber-glass reinforced plastics (FRP) applications, where the ethylenically unsaturated (this term refers to the ethylene double bond in the maleic acid) acids copolymerize with styrene monomer, contain larger amounts of the acids. All polyester resins may contain small amounts of monobasic acids such as benzoic or \textit{p-}tert-butylbenzoic acids which are used as chain regulators or terminators, and these are readily identified by GC as esters in the same determination as the major acids.

Polyester resins based on \textit{o-}phthalic acid in the liquid form are readily hydrolyzed by solution hydrolysis, but with isophthalic acid or with chemical modification, the ease of hydrolysis is dramatically reduced, while as a cured film the reaction is minimal. Using vigorous hydrolysis with molten alkali, simple alkyd and polyester resins, both as liquids and as films, are readily hydrolyzed, as are FRP laminates where the acids, polyols and the fiberglass may be determined concurrently. Similarly polyesters cross-linked with aminoplasts are cleaved. The aminoplast is liberated and appears as a sludge except where butylated ureaformaldehyde resin is used and this is degraded.

This later hydrolysis is carried out with a trifluoroacetic acid and trifluoroacetic anhydride mixture, with reaction for 2 h. The urea forms carbon dioxide and ammonium trifluoroacetate while the polyester forms polyl trifluoroacetates, with \textit{n-}butyltrifluoroacetate being formed from the butoxy groups. Other aminoplasts examined were melamine and benzoguanamine–formaldehyde resins which were cleaved from the polyester but not themselves cleaved. Figure 4 shows a series of chromatograms resulting from analysis of a soya oil alkyd cross-linked with 30% butylated urea formaldehyde resin.

![Figure 4](image-url)
Pyrolysis of alkyd and polyester resins has been reported, but the results are relatively poor and vastly inferior to those obtained with other techniques, and, as such, the procedure is not recommended. If speed of pyrolysis is desired, pyrolytic methylation is superior to direct pyrolysis.

11.2 Silicone Polyesters

Silicone polyester resins are extensively used in coil coating enamels and are produced by simple condensation of hydroxy and methoxy functional, low molecular weight silicone compounds coreacted with polyesters.

The resins are readily cleaved using 2 mg of resin and 100 mg of the prefused potassium hydroxide reagent. The fusion was conducted for 1 h at 250°C. The fusion was incomplete although qualitative results were obtained if the silicone polyester was examined as a film that had been cross-linked with an aminoplast. Total cleavage was achieved using trifluoroacetic acid and trifluoroacetic anhydride as fusion reagent. Figure 5 shows the separation of the products of degradation of a silicone polyester with simultaneous determination of the polyols, dicarboxylic acids and some species derived from the silicone portion of the polymer, all as trimethylsilyl derivatives.

![Figure 5](image)

Figure 5 Chromatogram showing simultaneous separation of polyols, dicarboxylic acids and silica as trimethylsilyl derivatives. Peak 1, solvent; peak 2, neopentyl glycol; peak 3, a type of silica species; peak 4, trimethylolpropane; peak 5, adipic acid; peak 6, isophthalic acid. (Reproduced from J.K. Haken, N. Harahap, R.P. Burford, *J. Chromatography*, 440, 329–332 (1988) with permission from Elsevier.)

11.3 Polyurethanes

The polyurethane molecule contains both carbonyl and amino functional groups and, while of considerable stability, is amenable to chemical degradation. In carrying out analyses, the level of residual isocyanate, which in most countries is subject to strict statutory limits, or the level of polyurethane composition, should be considered. Residual isocyanate may be determined by direct injection or by headspace analysis.

The polyurethane molecule is generally resistant to solution hydrolysis although systems containing long chain reactants have been successfully hydrolyzed. Vigorous hydrolysis using molten alkali gives rapid reaction, and cleavage has been obtained using reaction external to and within the gas chromatograph. Ether-type polyurethane cleavage is carried out with external fusion using alkali hydrolysis to liberate hydroxyl-terminated polyethers which are subsequently cleaved at the ether links by acid reaction to form low molecular weight fragments that are readily examined by GC. The molecular weight of the polyether may be determined on the isolated compound using size exclusion chromatography.

The polyurethane may be chain-extended by amines or diols and both may be determined. Often the same compound is obtained from the polyol present and from the polyether, and care in interpretation is necessary. In addition to polyethers from ether polyurethane, the reaction products obtained are a diamine corresponding to the diisocyanate, acetates of the polyols present and methyl esters of dicarboxylic acids.

Pyrolysis GC is the subject of several dozen reports and is readily conducted at 700–800°C. Early reports had some difficulty in differentiating between ester and ether-type polyurethanes but capillary column operation readily allows identification to be made. Pyrolysis GC of polyurethanes produces many fragments, is temperature dependent and never provides quantitative results.

The products are numerous and complex and include oxides of nitrogen, hydrogen cyanide, acetonitrile, acrylonitrile, pyridine, benzonitrile from the diisocyanate, carbon dioxide and specific fragments of the ester and ether components.

11.4 Epoxy Resins

Epoxy resins have been extensively examined by pyrolysis GC. The most widely used epoxy resins are based on bisphenol A or more recently bisphenol F. The major pyrolysis products are phenol, isopropenyl phenol and bisphenol A and if cross-linked with amino materials there are nitrogenous products. With bisphenol F the complex group joining the two benzene rings is absent and isopropenylphenol is not observed.
The epichlorhydrin does not produce any characteristic fragments.

Epoxy resins in the cross-linked state, while theoretically amenable to cleavage using vigorous conditions, have, on examination, produced unsatisfactory results. Pyrolytic methylation of epoxy resins in the uncross-linked state produces phenol, isopropenylphenol and the monomethyl ether of these compounds and of bisphenol A together with the diether of bisphenol A.

### 11.5 Polysiloxanes

Polysiloxanes are produced by the hydrolysis and polymerization of silanes. The materials have long been used as additives in coatings but are finding increasing use in the major film formers. In addition to use in silicone alkyls, combinations with epoxy resins are often used as heavy-duty coatings. Pyrolysis GC is readily carried out and a variety of methyl-substituted cyclic polysiloxanes are formed with dimethylpolysiloxanes. With low molecular weight products, cyclic products may be present before pyrolysis. If present, these low molecular weight oligomers may be determined separately by direct GC.

The polysiloxane bond is amenable to chemical degradation – hydrolysis with molten alkali being essentially quantitative. A number of atoms and functional groups are attached to silicon atoms and such derivatives find considerable use as reactive intermediates used in coatings. The organic constituent may be cleaved from the polymer to produce low molecular weight compounds that are readily estimated. The presence of small amounts of other alcohol groups, vinyl or aryl groups may be detected in dimethylpolysiloxanes. With either external reaction or reaction in situ, in a reactor attached to the gas chromatograph, alkalis produce silicates together with ethylene from vinyl groups, ethane from ethyl groups and benzene from aromatic groups. Many other procedures have been developed to determine the pendant vinyl content of polysiloxanes using the mineral acids. Alkoxy groups present are converted to the corresponding alcohol. Table 4 shows pendant groups commonly present, cleavage reagents and reaction products which are readily determined by GC.

With alkali fusion, the silicates may be converted to derivatives suitable for GC. Trimethylsilation of the liberated silicates is achieved by reaction of the silicic acids with bis-silyl trifluoroacetic acid (BSTFA) and trimethylchlorosilane (TMCS).

### 11.6 Polyamides

The best known polyamides are the nylons, which are not used in coatings. The nylons and polyamides in general are of two types, $\alpha$, $\omega$-aminocarboxylic acid condensates or diamine–dicarboxylic acid condensates. The dimer acid polyamides used as cross-linking agents in epoxy resin systems are of the latter type. The nitrogenous part of the polyamide pyrolyzes similarly to other aliphatic polyamides, producing a mixture of products including hydrocarbons, mononitriles, hydrocarbons and mononitriles containing an amide group, amines, dinitriles, cyclic ketones and lactams. The lactam fragment is a minor product as opposed to being the major or a major product of $\alpha$, $\omega$-aminocarboxylic acid condensates. The pyrolysis products show many degradation fragments from the long-chain fatty acids, for example C$_{36}$ with some C$_{18}$ and some C$_{54}$ mixed acids originally being present. The dimer polyamides are capable of pyrolysis at lower temperatures than nylons. When cross-linked with epoxy resins, the thermal stability is increased.

The polyamides are amenable to chemical cleavage by aggressive hydrolysis, and nylons which are of definite composition provide quantitative results. A small sample, i.e. 1–2 mg of polyamide, is reacted with 50–100 mg of potassium reagent at 250 °C for 0.5 h. The diamines are identified as trifluoroacetates and the fatty acids as dimethyl esters. Several dozen amines have been determined and are usually present in the polyamides as mixtures.

Aromatic polyamides and poly(amide–imide) are used in high-temperature-resistant coatings and have been subjected to both pyrolysis and chemical degradation, forming a wide range of products comparable to those of simpler homologs. Despite the thermal stability, the imide linkage is readily cleaved, with molten alkali generally forming esters of 1,2,4,5-tetracarboxylic acid.

### 11.7 Vinyl Esters

The vinyl esters incorporate some of the properties and reactions of polymers, epoxies and methacrylates, namely glycerol, bisphenol A and methacrylic acid, and products representative of each material are obtained on pyrolysis. The vinyl ester may be more effectively cleaved chemically, since the formation of methyl methacrylate is essentially quantitative. The terminal methacrylate moiety is hydrolyzed with molten alkali finally producing methylmethacrylate and the ether polyol. The ether is cleaved with acetic anhydride to form glycerol triacetate and bisphenol A diacetate. When this procedure is used with vinyl ester laminates, like polyester–fiberglass laminates or coatings containing glass flakes, it allows estimation of silica as an organic derivative.

### 11.8 Phenol Formaldehyde Resins

The chemistry of phenolic resins is very complex and the resins developed more than a century ago have found use in a myriad of applications, all of which are relatively minor. As such, these resins have not been as extensively examined as many other polymers using modern analytical techniques.

Phenolic resins are produced by the reaction of phenol or \( \text{para} \)-substituted phenols with formaldehyde to form methylol groups on the phenol rings. Condensation polymers are produced by reaction of the methylol groups to form methylene bridges with the elimination of water. Either alkali or acid catalysis may be used, the former being a slower reaction allowing isolation of the methylol phenols, the latter being much more rapid, with a cross-linked polymer being formed more rapidly.

The resins are not amenable to chemical cleavage, but have been extensively studied by pyrolysis. Pyrolysis products include both gaseous and liquid fragments and gaseous products include methane, carbon dioxide and carbon monoxide. Rupture of the weaker aliphatic carbon–carbon bonds occurs predominantly and as there are three possible methyl phenols and 16 possible polymethyl phenols, the products are numerous. Studies show that the constituent phenol/s appear as the major or a major fragment.

Blocked or \( \text{para} \)-substituted phenols have been introduced, including \( \text{para-tert} \)-butylphenol, \( \text{para-tert} \)-amylphenol and \( \text{para-nonylphenol} \). These reactants limit the possible reaction products and the phenols are evident in pyrolysis. Pyrolytic methylation has been used with the reaction products of these blocked phenols with formaldehyde. Pyrolysis of these resins produces the phenol and methyl and dimethyl phenols, while pyrolytic methylation produces the methyl ether of the phenol and the methyl ethers of the methyl and dimethylphenols, all of which elute before the three phenols.

### 11.9 Rosin Derivatives

Rosin is produced commercially as wood and gum rosin, the former from the stumps of trees, the latter from the gum of living trees. Solid rosin is approximately 90% rosin acids and 10% neutral material. Abietic acid, a monobasic acid containing a conjugated diene, is the major constituent, accompanied by a number of closely related acids.

Rosin is extremely reactive, forming esters with glycerol and pentaerythritol. The diene allows the Diels–Alder addition with maleic, fumaric and trimellitic anhydride, while oil solubility is achieved by reaction with phenol formaldehyde resins. Metal resinate soaps are formed by reaction with zinc oxide or calcium oxide. Cobalt, lead and manganese oxides produce resinate driers.

The pyrolysis of rosin and rosin products produces many fragments, the most characteristic of these being from rosin. The pyrolytic methylation of these products is considered superior, as multiple peaks of the rosin are obtained together with those of the reaction product. The major products of rosin are the methyl esters of abietic, dehydroabietic, pimaric and isopimaric acids. Esterified rosin glycerol produces the trimethyl ether, while pentaerythritol gives both pentaerythritol tetramethyl ether and pentaerythritol trimethyl ether. Polybasic acids form dimethyl maleate and dimethyl fumarate. Resins formed with \( \text{tert} \)-butylphenol and \( p \)-nonylphenol, formaldehyde and rosin, form characteristic rosin products together with methyl ethers of the phenol, of the methylphenol and of the dimethylphenols, all of which elute before the free phenols.

### 11.10 Cellulose and Derivatives

Cellulose is readily pyrolyzed and the major saccharidic degradation product is levoglucosan formed by scission of the 1,4-ether bridges between the structural units. This is followed by intramolecular rearrangement to produce a complex mixture of volatile low-molecular-weight compounds which include carbon monoxide, carbon dioxide, methane, ethane, ethylene, acetaldehyde, propionaldehyde, acrolein, methanol and water.

On pyrolysis, cellulose esters produce acetic acid from cellulose acetate, propionic acid from cellulose propionate and butyric acid from cellulose butyrate, in addition to products characteristic of cellulose.
When pyrolyzed, cellulose nitrate produces a complex mixture which includes nitrogen, oxides of nitrogen and carbon, hydrocarbons, aldehydes, esters and water. Cellulose and its derivatives are readily susceptible to chemical reaction—the esters may be transesterified, hydrolyzed by solution or molten alkali hydrolysis, with the reaction products determined by GC. Cellulose is partly alkylated to introduce solubility and the ethers are readily hydrolyzed, usually with dilute sulfuric acid, with the hydrolyzate being converted to methyl glucosides, using methanolic hydrochloric acid. Nine possible glucoside ethers are formed and all may be resolved using a short-packed polyester column. Hydroxyalkyl and carboxyalkyl celluloscs are similarly susceptible to chemical degradation. These products, like methyl and ethyl cellulose, are usually used in small concentrations, and the analysis of resins and paints containing cellulose ethers, by either pyrolysis or chemical degradation, is very difficult.

12 ADDITION SYSTEMS

Addition systems are finding greater use in coatings. Water-based architectural coatings are addition systems, as are acrylic automobile lacquers and many ultraviolet-cured finishes. Some major groups of resins used in coatings are shown below.

12.1 Polyolefins

The polyolefins alone are not generally used in coatings, although polyethylene is commonly used as a coating on food containers, while polyolefins generally are widely experienced as comonomers in many copolymer systems. Addition polymers commonly incorporate a carbon–carbon backbone and with the simplest polyolefin, polyethylene, the bonds are equivalent and rupture is random. The bond strength of the C–C bond is approximately 83 kcal mol\(^{-1}\) (347 kJ mol\(^{-1}\)) and of the C–H bond 94 kcal mol\(^{-1}\) (393 kJ mol\(^{-1}\)) and rupture of the weaker bond occurs. A large number of fragments result and the mechanism is described as random scission. The fragments produced have free radical ends and require stabilization. The fragment with a free radical may extract a hydrogen atom from an adjacent fragment and become a saturated end. Stabilization frequently occurs by \(\beta\)-scission where the induced free radical becomes an unsaturated molecule end. The process continues and produces a sequence of three hydrocarbons, the first saturated, the next with a double bond at one end, the third with a double bond at both ends. A series of \(n\)-alkanes, \(\alpha\)-olefins and, \(\alpha, \omega\)-diolefins up to carbon-number approximately 40 are formed, with the chromatogram showing an approximately normal distribution. In situ hydrogenation of the pyrolysis products of polyolefins is used, with hydrogen as the carrier gas and a precolumn containing a hydrogenation catalyst being inserted between the pyrolyzer and the column. In use the triplets become single peaks, with isocompounds of comparable structure forming single isoalkane peaks.

With polypropylene and other olefins such as isoprene, none of the C–C bonds are equivalent and a regular effect is not achieved. With polypropylene a series of diastereomers are formed and the polymer is synthesized with highly stereoregular structures—the various structures being readily detected by pyrolysis GC. Behavior is similar to polyethylene and a series of hydrocarbons with methyl branches is observed. The microstructure of polyolefins has been extensively studied and reviewed by several workers.\(^{24,25}\)

Polybutadiene is found in styrene–butadiene latices and the diene polymers may be linked in either the 1,4-position or the 1,2-position. The former has cis- and trans-isomers and the latter has different tacticities. The prevailing structures may be resolved by pyrolysis GC.

Polyisoprene or 2-methyl-1,3-butadiene finds some use in metal primers. The thermal degradation of natural rubber has been extensively studied. At low temperatures, isoprene dimerizes to dipentene, but at higher temperatures, little more than identifiable fragments are produced, together with a wide variety of products. Isomers are found as with butadiene, but more products are formed due to the complexity of the methyl group.

12.2 Polyethers

Alkylene oxide polymers are frequently hydroxyl terminated and are widely used as reactants in polyurethanes, while similar polymers are used in the myriad of alkoxylated long-chain surfactants that are available. Pyrolysis of these copolymers produces fragments characteristic of polyethylene, polypropylene and hybrid products of ethylene and propylene units. The ratio of ethylene and propylene is readily determined together with sequence distributions of the respective units. Pyrolysis with in situ hydrogenation leads to a simplification of the pyrogram—the saturated and unsaturated triplets of peaks forming single peaks.

Polyethers are susceptible to chemical cleavage; most mineral acids and some organic acids have been used for this. A few milligrams of sample are degraded by heating at 150 °C with a few milliliters of HBr in acetic acid to produce ethylene dihalide from polyoxyethylene products and propylene dihalide from polyoxypropylene products. A baseline separation of the ethylene and
propylene dibromides is achieved on a short packed column. Polytetramethylene ether as glycol is also used in polyurethanes, and chemical cleavage forms 1,4-butandiol diacetate. p-Toluenesulfonic acid and the mixed anhydride with acetic anhydride are effective cleavage reagents, with fewer by-products being formed than often occurs with mineral acids.

12.3 Polyvinyl Chloride
Polyvinyl chloride homopolymer does not find use in coatings, except plastisols, but is widely used in copolymers. Polyvinyl chloride degrades by a side-chain scission mechanism. The bond strength of the C–Cl bond is 73 kcal mol⁻¹ (305 kJ mol⁻¹), such that hydrogen chloride is readily split out leaving unsaturation in the chain. The unsaturated backbone fragments and produces aromatic compounds, of which benzene, toluene and naphthalene predominate. These fragments particularly are readily apparent in the pyrograms of copolymers because of their abundance.

12.4 Methacrylate Polymers
Methacrylate and acrylate polymers normally occur together and are generally termed acrylics. The two classes, while being close homologs, are treated separately, as the mechanisms of degradation are completely different. Methacrylates and other polymers possessing methyl substitution on thermal degradation revert almost completely to monomer by a process termed depolymerization, unzippering or monomer reversion. β-Scission with fragmentation occurs to form the monomer. The yield of monomer depends on the alkyl chain length, with methyl methacrylate and other short alkyl group polymers, the monomer yield is near 100%, but with long-chain polymethacrylates the yield is decreased due to some degradation of the alkyl chain. Pyrolysis GC of polymethacrylates is readily conducted and was first reported in the 1960s. Other polymers with α-methyl substitution such as α-methylstyrene also produce high yields of monomer.

The acrylic polymers are a class of vinyl polymers that are amenable to chemical degradation due to the presence of the pendant ester group. The backbone remains and analyses are of the pendant alkyl groups.

The Zeisel reaction has been used to determine the composition of acrylic copolymers. The pendant alkyl groups are estimated quantitatively as the alkyl halides. The resin is reacted with hydriodic acid in phenol and the halides formed are separated by GC. A packed polyester column resolves the methyl, ethyl and butyl esters using a low temperature, i.e. 70–75°C. 2-Ethylhexyl acrylate is frequently used in coating terpolymers and this halide together with the lower homologs is readily separated using temperature programming. A limitation of the procedure is where the same alkyl acrylate and alkyl methacrylate are used – the two compounds are resolved together as the same alkyl halide. The procedure is applicable where acrylic and other esters are present.

The polymethacrylates are resistant to solution hydrolysis, but are readily cleaved by fusion with molten alkali to form the corresponding alcohol and the alkali metal salt.

12.5 Acrylates
The acrylate esters although producing less than 5% monomer on pyrolysis, do produce a series of saturated and unsaturated oligomers. Both series produce homologous saturated and unsaturated compounds, and these compounds have been detected as dimers, trimers, tetramers and pentamers and thus a particular acrylate ester produces many characteristic compounds.

The acrylates are also amenable to Ziesel-type cleavage and to cleavage with molten alkali as detailed above for the methacrylate esters. Longer chain polycrlylates have been degraded by solution hydrolysis but the digestion times required are extremely long and the analysis is considered unsatisfactory.

12.6 Polystyrene
Polystyrene is used in coatings both in condensation systems, i.e. as styrenated alkyds, and more extensively as a comonomer in addition polymerization systems. Polystyrene degrades by a complex mechanism, producing approximately 40% monomeric styrene depending on the temperature and the dimer and trimer. The dimer fraction is a complex mixture of structural isomers: about 20 peaks corresponding to the molecular formula C₁₆H₁₆ have been partly identified by MS.

12.7 Polyacrylonitrile
Polyacrylonitrile because of its insolubility is not used as a coating, but is widely used as a comonomer in combination with styrene, butadiene and vinyl systems. The polymer degrades on pyrolysis, the reaction products and their concentrations being dependent on the temperature. The products include ammonia, hydrogen cyanide, methacrylonitrile, acetoniitride and monomer. At lower temperatures cyanogen and vinylacetonitrile are also produced together with traces of benzene, toluene and pyridine derivatives. With polyacrylonitrile pyrolysis, some complex nitrogenous materials always remains. Pyrolysis GC with MS detection readily determines fragments characteristic of polyacrylonitrile.

Polyacrylonitrile is amenable to chemical cleavage. With hydrolysis with molten alkali, the nitrile pendant
group is cleaved essentially quantitatively and is determined as ammonia.

12.8 Polyvinyl Acetate

Polyvinyl acetate homopolymer is now rarely used in coatings, although copolymers containing 5–20% of acrylate esters are widely used, while copolymers with other esters find limited use. Of more recent origin are ethylene–vinyl acetate copolymers used extensively in adhesives. Polyvinyl acetate degrades by side-chain scission, with acetic acid being liberated and readily determined, together with benzene and toluene.

Higher homologs of vinyl acetate are available, and when degraded produce the corresponding acids which may be resolved concurrently.

12.9 Polyvinyl Alcohol

Polyvinyl alcohol, usually resulting from the hydrolysis of polyvinyl acetate and usually containing some unhydrolyzed ester, is widely used in emulsion systems. When pyrolyzed yields mainly water and acetaldehyde and usually acetic acid from unhydrolyzed polyvinyl acetate present. This type of degradation is typical of side-chain scission.

13 GENERAL ANALYTICAL SCHEME FOR RESINS

A complete analysis of many coating materials is a daunting and often impractical task, but with experience, the desired information can usually be obtained. A myriad of analytical techniques are available and for specific determinations a number of techniques are used. It is pointless to attempt an analysis using a single major technique. For coating analysis in general, three techniques are first applied, namely infrared spectroscopy, GC and liquid chromatography. All are techniques which are applied quickly and hence many hours of expensive time are not required, as with gravimetric analysis. The cost of the instruments needed for application of the three techniques is relatively low. The first step in a coating analysis is the determination of the infrared spectrum. If the resin is soluble in solvents, this uses transmission techniques, if insoluble or as a film, conventional reflectance or Fourier transform infrared techniques may frequently be used. From the spectrum the functional groups present are readily determined, and a strategy of further analyses may be determined.

Pyrolysis GC rapidly provides a pyrogram which may contain a few, although frequently many, component peaks. The peaks that are present or the absence of a particular peak or peaks provide much valuable information about composition.

Mass spectrometers are widely used and available in most laboratories. Attachment to the gas chromatograph allows detailed or sufficient information to be obtained about each pyrolysis peak as it is resolved. Bar charts, compilations and books of polymer pyrograms have been available since the 1960s, but are of little value as modern resins are extremely complex and the pyrogram often provides a huge amount of data. Programs are available or may be developed employing a database of pyrolysis GC data or the mass spectra produced to allow the identification of an unknown resin. The database need only be restricted, as it soon becomes apparent that a sample type is not included. The database may be accessed with regard to a specific type of resin or may be quite general.

It is generally possible to determine the basic composition from the infrared spectrum of the resin and from identification of the pyrogram fragments. From the information available, the value of utilizing chemical degradation or other analytical techniques is apparent.

14 QUANTITATIVE NATURE OF RESIN DEGRADATION

With few exceptions, notably the \(\alpha\)-methyl substituted polymers such as the polymethacrylates, pyrolysis is not quantitative, but often produces an array of products. The products are extremely valuable in identifying the resin and also in showing the resin structure. A simple mixture of equal weights of polyacrylate homopolymers does not produce the same pyrogram as a copolymer containing equal weights of the comonomers. The particular value of pyrolysis GC is the small sample required, the rapid time of analysis and the capacity for rapid identification using coupled MS.

Chemical degradation or cleavage has been found to be essentially quantitative; early studies showed that errors were introduced in the extraction and separation steps used in the derivative formation steps, but with elimination or reduction in the number of these steps, the errors are reduced or minimized. The sample size required is little greater than for pyrolysis, but the reaction time both for the degradation and the workup is much greater. A limitation of chemical degradation is that some of the initial reactants are mixtures and the reconstituted products or their derivatives are similarly mixtures. In resins, however, some of the functional classes are essentially pure and the overall composition can be established. Table 5 shows resin types that are chemically degraded,

together with the products isolated and limitations of analysis.

Pyrolytic methylation is related more closely to pyrolysis than to chemical degradation. The sample size, apparatus and time required are the same, but species not resolved or poorly resolved by GC are converted into derivatives more suitable for GC. The technique is temperature dependent and is not quantitative because a series of partial ethers and esters are formed in some analyses. The technique, however, greatly extends the value of pyrolysis.

15 FORENSIC APPLICATIONS

GC is an ideal tool for use in forensic science because only a small sample is required and the sensitivity is high. Numerous uses of GC exist in forensic science but two major applications concern the examination of coating fragments from accident or crime scenes and the examination of solvent residues from material used as accelerants in arson investigations. Coating examination has been the topic of numerous reports, the vast majority involving pyrolysis GC. Case work has utilized samples of 1 µg, but usually slightly larger samples are used. Both pulse mode and furnace type pyrolyzers are used. Pyrolytic methylation may also be used by the coatings analyst and has been extensively employed in the forensic examination of coating samples.

While automotive fuel or refined petroleum is widely used as an accelerant, the residue after ignition and/or after weathering due to the accentuated loss of the lower boiling components is such that the chromatogram of the sample bears little resemblance to the chromatogram of the initial fuel. Other accelerants include alcohols, where the denaturant is frequently concentrated and higher boiling petroleum fractions with comparable homologs including kerosene, white spirits and mineral turpentine. Lacquers, lacquer thinners, solvent-based wood stains and plastics have all been detected in accelerant investigations by GC.

Other related uses of GC concern the examination of nail lacquers, waxes, automotive body putties and fatty acids. The topic has been the subject of several reviews.\(^{27,28}\)

16 ARCHAEOLOGICAL USES

GC, usually in association with pyrolysis and MS, has become a standard tool in the examination of coatings on ancient objects, including buildings, art works and funeral works. Organic media, including gums, waxes, naturally occurring resins and synthetic polymers, are frequently examined. Pyrolytic methylation is used as a replacement for simple pyrolysis – low volatility products being converted to esters or ethers and facilitating or allowing gas chromatographic analysis.

Fatty acids and triglycerides have been extracted from coating samples and from human remains that have dated from biblical times. Several reviews\(^{29,30}\) have appeared, prepared by leading groups of researchers.

17 ART FRAUDS AND CONSERVATION

The investigation of the authenticity of art works and antiques is widely employed and some notable forgeries have been uncovered. Studies frequently employ pyrolysis and pyrolytic methylation and the techniques employed are analogous to those used in forensic and archeological studies.
In conservation and restoration studies the same techniques can be employed. It is often essential to have knowledge of the extent of prior restoration and the degree and type of the overcoat varnish before further restoration is commenced.

**18 HEADSPACE ANALYSIS**

Headspace analysis is the examination of an equilibrium mixture of volatile materials in a gaseous mixture, the procedure being widely used in the investigation of coating problems associated with packaging. Many food products, including nuts, chocolate and biscuits, are packaged in plastic containers, frequently clear but also in multilayer or laminated films. The packages are printed with inks or coatings which contain solvents, and similarly adhesives used to laminate films usually contain solvents, as do many clear plastic films.

Residual solvents often not detected by the nose, equilibrate on storage, are released into the usually sealed container, and are often transferred to the food, causing the food to be tainted or to assume an abnormal taste. The residual solvents may be readily detected by headspace GC. By the use of suitable controls it is often possible to determine if the solvent has come from the coating or from which coating in a multicolored system: the adhesive or the plastic film. Solvents not conventionally used in coatings, such as tetrahydrofuran or dimethyl formamide, have been found in food products and wrappers and are used in the manufacture of plastic films.

The technique may employ simple laboratory constructed apparatus, which may simply be a perforated metal lid on a screw-capped glass jar fitted with a silicone washer, or a lid with an injection port, or alternatively a dedicated commercially available headspace gas analyzer. Plastic lids and lids with polymer seals are to be avoided as these frequently liberate volatiles on heating and lead to spurious results. The glass vessel should be relatively small, typically 100–150 mL to avoid considerable dilution or the use of a large sample. The sample in the jar is heated in an oven to 100–200°C for 0.25–1.0 h and a gas sample injected into the chromatograph. Conditions depend on the particular sample and it is essential that controls be used and that the sample and controls be examined under the same conditions. Capillary GC with mass spectroscopic identification of the products is desirable as peaks characteristic of the food concerned are often detected.

The technique has been the subject of several monographs.\(^{31,32}\)

**19 INVERSE CHROMATOGRAPHY**

Many hundreds of reports have appeared concerning inverse GC, a variant of simple GC where the column is packed with polymeric or resinous materials, many of which are used in coatings. Simple molecules are used as solutes and while thermodynamic parameters are determined, the technique is considered to have little general utility and to be of negligible value to the coatings industry.

1 INTRODUCTION

The primary difference between IR spectroscopy of polymers and IR spectroscopy of polymers deposited on substrates is that while analysis of the former may be a relatively straightforward task, the latter is usually more challenging. This is because when a polymer is deposited on a substrate, usually referred to as an organic coating, more sensitive and selective spectroscopic analytical techniques are required. These analyses may often be accomplished by either removal of a polymeric coating from a substrate, or utilization of analytical techniques that overcome this requirement. Ideally, one would like to have a nondestructive means of analysis that would provide qualitative and quantitative information. Because such approaches require high-energy throughput, selected surface-sensitive IR spectroscopic approaches have been developed in conjunction with Fourier transform infrared (FTIR) and Fourier transform (FT) Raman spectroscopy.

The advantages of FTIR spectroscopy, in comparison to dispersive techniques, include the Jacquinot,\(^1\) Fellgett,\(^2\) and Connes\(^3\) advantages. While the Jacquinot advantage arises from a greater energy throughput from the source, thereby improving signal-to-noise ratio,\(^4\) the Fellgett advantage derives from the ability to collect all frequencies from a single scan. In contrast, dispersive instruments acquire the spectrum by measuring the intensity of one frequency at a time. The Connes advantage arises from the monochromatic laser used as a standard reference to effectively control the optical retardation, allowing co-addition of scans in an experiment. In essence, this feature reduces the error of mirror position resulting from a series of scans, therefore minimal spectral artifacts are produced by the co-addition of scans.

A Michelson two-beam interferometer, shown in Figure 1, is the basic design used in most modern FTIR spectrometers.\(^5\)\(^,\)\(^6\) In this interferometer, IR light is split into two orthogonal beams by a beamsplitter, where one beam strikes a movable mirror, and the other impinges on a stationary mirror. Reflection of the radiation from these mirrors returns to the beamsplitter, where light interference due to recombination produces a collimated beam of given intensity directed toward a sample. Modulation of the IR light intensity, which generates an interferogram of intensity as a function of time, is accomplished by changing the optical retardation (i.e. by displacing the movable mirror position) of the light.

The interferogram is represented as the sum of all cosine or sine waves multiplied by a factor reflecting the intensity for all wavelengths from a polychromatic source during one movement of a mirror, that is one scan.\(^4\) The relationship between light intensity for a

given wavelength of light is expressed as Equation (1):

\[ I(\delta) \propto \sum_{\lambda = \infty}^{\lambda = \infty} I_\lambda \cos \left( \frac{2\pi \delta}{\lambda} \right) \]  

(1)

where \( I \) is the light intensity, \( \delta \) is the optical retardation, and \( \lambda \) is the wavelength of light. Conversion of the interferogram to the frequency domain is accomplished by moving the movable mirror at a constant rate, followed by multiplying the mirror velocity (in centimeters per second) by the optical retardation (in centimeters). Separation of the interferogram into its resolved cosine/sine waves is achieved by a FT, which expresses the intensity of light as a function of energy of IR radiation, which is an FTIR spectrum. Due to overwhelming advantages of this interferometric approach over dispersive methods, FTIR is used in surface and interfacial analysis of organic coatings.

In analysis of polymeric films and coatings there are three special directions of analysis. Figure 2 schematically illustrates \( x \), \( y \), and \( z \) directions and correlates the most desirable surface techniques with the direction of analysis. While the \( z \) direction may be effectively analyzed using ATR, RA and PA techniques, \( x-y \) directions can be imaged using FTIR and FT Raman microscopy/imaging in conjunction with surface selected methods. This choice is dictated by their ability to carry out a nondestructive analysis, and qualitative and possibly quantitative surface and interfacial molecular level analysis. The following sections describe principles and selected applications utilized in analysis of polymeric films and coatings.

## 2 ATTENUATED TOTAL REFLECTANCE SPECTROSCOPY

ATR belongs to a category of internal reflection spectroscopy which utilizes an IR transparent crystal of higher refractive index in contact with a sample to measure optical spectra. The intensity of IR light that passes through the crystal is dictated by the critical angle (\( \theta_c \)), defined as \( \sin^{-1} \frac{n_2}{n_1} \). Refractive index differences between the crystal \( (n_1) \) and sample \( (n_2) \) cause the light to reflect inside the crystal when \( \theta > \theta_c \), and refracts out of the crystal for \( \theta < \theta_c \). This is schematically illustrated in Figure 3. Expounding upon the internal reflection element, numerous configurations examining a wide variety of samples can be analyzed.\(^7\)

When the sample absorbs a portion of radiation, the propagating wave is attenuated. ATR is a contact method (Figure 4a), where the IR beam is directed at an

incident angle ($\theta$) through a crystal of refractive index $n_1$ onto a sample of refractive index $n_2$. Using polarized IR light, as shown in Figure 4(b), the orientation of surface functional groups can be determined.$^{(8)}$ The TE wave is defined as having its electric vector parallel to the plane, whereas the TM polarization has an electric vector perpendicular to the plane according to convention.$^{(9,10)}$ ATR is a surface-sensitive technique commonly utilized to determine surface information from polymeric samples.$^{(7,11)}$

One of the main advantages of ATR is the ability to perform surface depth-profiling experiments from 0.2 to 5 µm. This is accomplished by variation in the angle of incidence and/or utilizing ATR crystals with different refractive indices. The penetration depth, $d_p$, is given by Equation (2):$^{(7)}$

$$d_p = \frac{\lambda}{2\pi n_1 (\sin^2 \theta - n_{21}^2)^{1/2}}$$  \hspace{2cm} (2)

where $n_{21}$ is the refractive index ratio of the sample and crystal ($n_2/n_1$), and $\lambda$ is the wavelength of electromagnetic radiation. However, it should be kept in mind that although this relationship is quite useful, due to optical effects resulting from optical effects between the sample and the crystal, it cannot be used directly. Furthermore, because Equation (2) was derived for homogeneous samples, any variation of surface concentration or conformational changes will invalidate this relationship. The following sections describe ways to get around this problem.

ATR spectra are a complex function of absorption and refractive index spectra, which incur optical effects between the ATR crystal and sample as a result of contact. To account for these effects, ATR spectra are converted to optical constants, followed by conversion to Beer–Lambert absorbance spectra. While detailed description of the entire process is documented in the literature, a schematic diagram of the algorithm is shown in Figure 5, and it is based on a double Kramers–Kronig transform (KKT).$^{(12,13)}$

Although the above correction methodology provides meaningful data, as indicated earlier, quantitative analysis in terms of surface depth profiling is limited because Equation (2) was derived for homogeneous surfaces. In other words, if there are surface concentration changes, this useful relationship, which allows the angle of incidence and the refractive index of a crystal changes to perform a surface depth profiling experiment, cannot be used. In an effort to account for this phenomenon, the following approach was developed. The surface is numerically sliced to form a stack of parallel thin homogeneous films. The films are homogeneous within each layer, but the layers among themselves are not. Thus, Equation (2) can be applied to each layer, and applying

![Figure 4](image1.png)

![Figure 5](image2.png)  

**Figure 5** ATR algorithm utilized to correct ATR spectra for optical distortions. (Adopted from Urban.$^{(11)}$)
well-established reflectivity optical theory for each layer and step-wise treatments, one can obtain distribution of the species for nonhomogeneous surfaces. Figure 6 illustrates the reflection of light propagating in the $x$–$y$ plane at the boundary between ATR crystal and an $N$-phase sample stratified into $z$ layers. Each layer has a thickness of $h_j$ and refractive $n_j = n_j - ik_j$.

ATR surface depth profiling was used to elucidate stratification of organic coatings in numerous systems, including melamine-polyesters, alkyls, urethanes, and latexes. Using ATR FTIR quantitative aspects of polyurethane (PUR) formation, including stratification of individual components as well as kinetics of crosslinking reaction near surfaces and interfaces can be studied. For example, Figure 7 illustrates NCO concentration changes plotted as a function of reaction time for urethane reactions conducted at different humidity conditions. As seen, the relative concentration of the NCO groups changes not only as a function of time, but also as a function of depth from the film–air and film–substrate interfaces.

Quantitative aspects of ATR were fully explored in the studies of biological systems where thin, organic multi-layers were attached to poly(vinyl chloride) (PVC) in order to chemically bond antithrombocytic layers of heparin. While the ultimate goal of these studies was to prevent blood cluding of artificial organs made out of PVC, one of the interesting aspects of this analysis was discovery that depending upon an application method,
heparin molecules may align parallel or perpendicular to the surface. As shown in Figure 8, application of higher shear rates results preferentially in parallel orientation of heparin to the surface. In these studies the ATR configuration illustrated in Figure 4(b) was used.\(^{(20-30)}\)

### 3 REFLECTION–ABSORPTION INFRARED SPECTROSCOPY

While details concerning applications and theory of reflection–absorption infrared spectroscopy (RAIRS) can be found in the literature.\(^{(31)}\) Figure 9 illustrates a schematic diagram of a typical RAIRS measurement configuration,

where IR polarized light hits the surface of a metal substrate and reflects off. In RAIRS experiments, only those dipoles that are aligned with the electric vector of the incident light, or with the direction of polarization, will interact with the light, resulting in an absorption band and providing information about the orientation of molecules at a surface. In contrast, for a thin film with randomly oriented molecules, all active dipoles will contribute to the spectrum. The earliest use of IR reflection spectroscopy to characterize adsorbed monolayers on metal substrates were measurements performed by Pickering and Eckstrom\(^{(32)}\) and Francis and Ellison.\(^{(33)}\) These as well as other measurements were made using a multiple reflectance approach as a means to enhance interactions with the thin film and give more intense absorption bands.\(^{(34-37)}\) However, the optimum experimental conditions were established by Greenler,\(^{(38-40)}\) who determined that only a single reflection was necessary for angles of incidence close to 88°. While Greenler\(^{(41)}\) formulated the early theory for RAIRS and demonstrated the underlying physics that allowed us to understand the enhancement in the response from a thin surface layer for p-polarized measurements, the most recent monograph by Claybourn\(^{(42)}\) provides an excellent overview of the current status of RA spectroscopy.

Figure 10 shows the expected reflectivity as a function of the angle of incidence for a three-phase system at 1000 cm\(^{-1}\). The s-polarized component, \(R_s\) is very close to 1 because there are negligible interactions with the film. However, in the \(R_p\) curve, there is a minimum at a grazing angle close to 88°, that corresponds to a strong coupling with the coating. If one uses Greenler’s description of an absorption factor \(A\) defined for s- and p-polarizations as shown in Equations (3) and (4):

\[
A_s = \left[ \frac{R_o R_s}{R_s} \right]
\]

where \(R_o\) is the reflectance of the bare substrate.

![Figure 8](image-url)  
**Figure 8** ATR FTIR spectra in the O–H bending region for heparin reacted with a PVC surface at various shear rates. (Reproduced by permission from Kim and Urban.\(^{(19)}\))

![Figure 9](image-url)  
**Figure 9** Schematic diagram of a typical RAIRS measurement configuration, where IR polarized light hits the surface of a metal substrate and reflects off. (Reproduced by permission from Claybourn.\(^{(31)}\))

![Figure 10](image-url)  
**Figure 10** Reflectivity plotted as a function of the angle of incidence for s- and p-polarized light. (Reproduced by permission from Claybourn.\(^{(31)}\))
the absorption by the film can be estimated as a function of the angle of incidence. The meaning of $R_0$ and $R_s,p$ is shown in Figure 11(a). Figure 11(b) illustrates the absorption factor for s- and p-polarized light obtained using the same parameters for the reflectivity calculations depicted in Figure 10. From this simple calculation for a three-phase system, there is a strong enhancement only for p-polarization in the absorption factor for the surface film at grazing angles. If this is compared with the results shown for a 100 nm poly(methyl methacrylate) (PMMA) film in Figure 12 taken at normal incidence, no spectral signal is present, as one would expect from Figure 11(b). This is because $A_{s,p} \approx 0$ at this angle of incidence.

RAIRS can be used for studying the behavior of thin films on metal substrates, how they bond to the metal, structural ordering, and modifications with sample processing. Garton\(^{43}\) examined the chemical binding of sulfonated polystyrene to a polished copper substrate. Figure 13 shows the RAIRS spectrum for this sample consisting of a 100 nm film of the polymer. The apparent absence of the band at 1101 cm\(^{-1}\) due to the sulfonic acid groups is obvious, and the presence of the bands at 1008 cm\(^{-1}\) and 1126 cm\(^{-1}\) due to sulfonate results from the acid conversion to salt at the copper surface.

This technique can also be used for monitoring chemical and physical processes. Kurth and Bein\(^{44}\) have used RAIRS for studying the hydrolysis and condensation reactions of siloxanes on gold. Figure 14 shows the RAIRS data for a film undergoing thermal processing, which initially forms low molecular weight oligomers followed by a low degree of crosslinking. This is expected because a monolayer would not give the same level of crosslinking as the bulk material, where the molecular interactions occur in three dimensions. Duevel and Corn\(^{45}\) have used phase modulation (PM) RAIRS to study the amide and ester derivitization of alkanethiols on gold surfaces.
INFRARED AND RAMAN SPECTROSCOPY AND IMAGING IN COATINGS ANALYSIS

Figure 14 RAIRS spectra of hydrolysis and condensation reactions of siloxanes undergoing thermal processing on gold. (Reproduced by permission from Claybourn.\textsuperscript{(31)})

Naselli et al.\textsuperscript{(46,47)} have studied the thermal processing of cadmium arachidate films on silver substrates, and demonstrated that at room temperature the molecules are oriented, with progressive disordering of the molecules even below the melting temperature of 110 °C. This type of application can give insight into the structuring of polymeric materials at polymer–metal interfaces. RAIRS is potentially an important technique for characterization of binding of coatings to metal substrates.

The above examples illustrate the feasibility of RAIRS for characterization of thin films on metal substrates. Because not all samples are conveniently deposited on highly reflecting, optically flat metal substrates, it is also important to be able to utilize RAIRS in other sampling situations. Monolayers, in particular Langmuir–Blodgett films or self-assembling layers, have applications as boundary lubricants, such as component layers in electrical and optical devices. In these cases, the substrate is not a metal, and RAIRS has been used for studying thin films on semiconductors\textsuperscript{(48–51)} and water.\textsuperscript{(52–56)} In the case of water being a substrate, many polymers, surfactants, proteins, and other species are deposited on water, and such experiments require in-situ characterization. Dluhy and Cornell\textsuperscript{(57)} first demonstrated the facility for characterizing monolayers at an air–water boundary using RAIRS. In this case, expected reflectivities for s- and p-polarized light can be calculated from the Fresnel equations for a three-phase system.\textsuperscript{(31)} If one considers a 100 Å film with \(n_2 = 1.5 + 0.1i\) on water with \(n_3 = 1.44 + 0.03i\), the expected reflectivities as a function of angle of incidence in the C=O spectral region are shown in Figure 15. For comparison, behavior of a similar film on a metal surface (\(n = 3 + 30i\)) is also illustrated. For metal substrates, both s- and p-polarized reflectivities remain high, with \(R_s\) close to unity for all angles of incidence, and \(R_p\) close to unity except at grazing angles where there is a sharp dip. Reflectivities for an air–film–water system are much lower, but rise sharply at higher angles.

4 PHOTO-ACOUSTIC FOURIER TRANSFORM INFRARED SPECTROSCOPY

The first PA experiment was discovered over a century ago by Alexander Graham Bell while investigating various forms of optical communications.\textsuperscript{(58,59)} In Bell’s experiments, the modulation of sunlight directed onto an absorbing sample produced an audible sound capable of
being detected by an observer positioned away from the apparatus. At the time, Bell recognized that his discovery may be used to investigate IR absorption spectra of various materials. Bell’s initial experiments were later followed by Tyndall and Röntgen, who discovered that a gas enclosed in a cell can produce an acoustic signal when modulated by a light source.

The technique remained relatively unknown until its renaissance in the 1970s. The development of FTIR, low-noise electronics, and improved detector sensitivity during the 1980s caused a renewal of interest in photoacoustic spectroscopy (PAS), which proved to be a unique and valuable analytical technique.

In PA FTIR, modulated IR light is absorbed by a sample, followed by nonradiative de-excitation processes converting light to heat. Thermal waves produced within a depth \( x \) travel to the sample surface, periodically heating an adjacent, inert gas atmosphere directly above the surface. A microphone within the gas atmosphere detects pressure fluctuations produced by this periodic heating of the sample, and subsequent Fourier transformation of the interferogram generates PA FTIR spectra. An illustration of a PA cell, along with frequently used parameters in the signal detection, is shown in Figure 16.

Thermal waves evolving from a depth \( x \) are proportional to \( e^{-ax} \), where the thermal diffusion coefficient, \( a = \mu_\alpha^2 \); therefore, thermal wave amplitude is reduced by a factor of \( e^{-1} \), \( e^{-2} \), and \( e^{-2\pi} \) at distances of \( x = \lambda_\beta \), \( 2\lambda_\beta \), and \( 2\pi\lambda_\beta \) into the sample, where the optical absorption length, \( \lambda_\beta \), is defined by Equation (6):

\[
\lambda_\beta = \frac{1}{\beta(\tilde{\nu})} \quad (6)
\]

After the internal conversion of light to heat occurs within a sample, thermal waves propagate from a depth determined by the thermal diffusion length, \( \lambda_\mu \), defined by Equation (7):

\[
\lambda_\mu = \left( \frac{\alpha}{\pi f} \right)^{1/2} \quad (7)
\]

where \( f \) is the Fourier frequency, and \( \alpha \) denotes the thermal diffusivity of the sample, which is represented by Equation (8):

\[
\alpha = \frac{\kappa}{\rho C_p} \quad (8)
\]

where \( \kappa \) is the thermal conductivity, \( \rho \) is the density, and \( C_p \) denotes the heat capacity at constant pressure.

- **Figure 16** Schematic diagram of (a) a PA cell and (b) parameters involved in the signal detection.
low thermal expansion coefficients. Therefore, for quanti-
titative purposes, the TPM is often used as a reference to
count for various PA effects in polymers.\(^{71–75}\)

Other theoretical approaches of PAS for nonhomo-
geneous samples have been derived from the TPM
theory using the PA signal magnitude.\(^{76–78}\) Grosse and
Wynands\(^{79}\) used a general expression for the surface
temperature to simulate a PA spectrum sample with
any number of homogenous lamellae with various opti-
cal and thermal properties. This theory accounts for
multiple reflections occurring within the sample cham-
ber as well as thermal wave interference using matrix
calculations.

4.1 Photo-acoustic Experimental Methods

Two modes of data collection for PA FTIR experiments
are continuous-scan (CS) and step-scan (S\(^2\)), where the
primary distinction between methods depends on whether
the modulation frequency is varied, or constant for a given
wavenumber. In CS PAS mode, the
interferometer mirror moves at a constant velocity for
all retardation points, resulting in a different modulation
frequency for each wavenumber. Conversely, the mirror
moves incrementally to each retardation point in S\(^2\)
PAS experiments, where application of a constant
light frequency eliminates spectral multiplexing of the
instrument often found when using CS PAS.\(^{81}\)

The S\(^2\) PAS experiments can be further classified,
according to the method used to produce a modulated
light waveform, as amplitude modulation (AM) and
PM.\(^{82}\) In AM experiments, a mechanical beam chopper
produces modulated radiation, whereas PM utilizes oscil-
lation of the interferometer mirror back and forth across
a set point (light interference) for signal generation. Both
methods effectively modulate the IR light source, but PM
allows continuous irradiation, resulting in a higher signal-
to-noise ratio. Moreover, AM experiments produce a
large direct current offset, resulting in substantial noise
contributions outside the zero-path-difference point of
the interferogram, i.e. the “wings” on the sides of the
centerburst region, creating significant spectral artifacts.

Equation (8) illustrates a straightforward method of
sample depth profiling using PAS, which is obtained by
manipulating the Fourier frequency dependence of \(\mu_\alpha\).

Figure 17 shows the spectra obtained at 0\(^\circ\) phase shifted
\((I)\), and 90\(^\circ\) phase shifted \((Q)\), with respect to the inci-
dent radiation waveform, which can be mathematically
processed to increase spatial resolution. The \(I\) spectra
represent molecular information closer in proximity to
the surface, whereas the \(Q\) spectra evolve primarily from
the specimen bulk. Both spatially distinct spectra are
easily extracted from a PA experiment by employing a
digital-signal-processor or lock-in-amplifier.\(^{83,84}\) With
these mutually orthogonal component spectra, spatially
dependent PA phase information, such as PA signal phase
and phase rotation spectra, are made possible.

A physical interpretation of the PA signal phase is
the time delay for thermal diffusion to occur, and the
subsequent generation and detection of an acoustic
wave. Layers deeper within a sample are resolved
from shallower layers by the presence of larger phase
shifts from the source radiation. The degree of phase
shift can be measured using phase spectra, which are
used to determine PA signal depth, especially when a
nonabsorbing top layer is present in conjunction with
an absorbing bottom layer at a given wavenumber.\(^{85,86}\)
Phase spectra are mathematically derived by applying an
arctangent function on the \(I\) and \(Q\) spectra for all
wavenumbers, as shown in Equation (10):

\[
\theta = \tan^{-1}\frac{Q}{I} \tag{10}
\]

Similar to the PA signal phase, phase rotated spectra
employ both \(I\) and \(Q\) spectra as well. As shown in
Figure 17, two signals are projected onto a specific angle,
\(\phi\), to acquire angle-dependent spectra. Furthermore,
phase spectra allow calculations of the PA signal phase
delay with respect to the source, whereas phase rotation
spectra determine the intensity of a band as a function of
\(\phi\) using Equation (11):\(^{87}\)

\[
M(\phi) = I \cos(\phi) + Q \sin(\phi) \tag{11}
\]

Previously, few methods have explored the possibilities of
using phase rotated spectra due to a limited knowledge of
this angle specific information. Although several recent
studies investigated the capabilities of depth-profiling
with phase spectra, there are discrepancies in this theory. The major problems include collection angle determination, correlating data obtained from different frequencies, and determining spatial resolution of phase rotated spectra.

### 4.2 Continuous-scan Photo-acoustic Methods

Because early spectrometers lacked the sophistication of current instrumentation, CS PAS methods were more commonly used for data collection. Due to its ability to obtain spectra for highly opaque samples, the first PA experiments established the usefulness of this technique for the characterization of polymers. In spite of the fact that CS PAS methods were the earliest types of PA experiments performed, a significant amount of current research employs this technique.

During the 1980s, CS PAS was established as a viable method of polymer characterization with unique attributes, such as minimal sample preparation, and a wide scope of possible analytes, as opposed to other IR techniques. Some of the earliest studies of PAS showed the depth-profiling capabilities of this technique for both ultraviolet/visible and IR regions. One particular study displayed the ability to depth-profile layered polymer films by changing the mirror velocity of the interferometer, thereby changing the modulation frequency for each data set. Ultimately, changing interferometer mirror velocity allows control of recorded surface or bulk information by manipulating the experimental thermal diffusion length, \( \mu \). In these studies, the spectra from a layered system of poly(vinylidene difluoride) (PVDF) on poly(ethylene terephthalate) (PET), recorded at mirror velocities of 0.15, 0.30, 0.60, 0.90, and 1.20 cm s\(^{-1}\), showed the presence of the PET carbonyl contribution (1738 cm\(^{-1}\)) at low mirror velocities (greater thermal diffusion lengths).

A similar study, using the mirror velocity dependence of the experimental thermal diffusion length, investigated treatments of PET fiber with a poly(ethylene oxide) (PEO) block copolymer. From spectra of the treated and untreated samples collected at four mirror velocities, the intensity of the CH stretch (2880 cm\(^{-1}\)) of the PEO copolymer increased with mirror velocity, demonstrating a higher concentration of PEO copolymer at the surface.

Applications of CS PAS have proven to be an effective method for determining component stratification from a study of thermoplastic olefins (TPO), which are extensively used in automotive applications. These injection-molded polymers consist primarily of polypropylene (PP), with ethylene–propylene rubber (EPR), and talc filler. Characterization of various components were performed utilizing the IR bands at 2953 and 2849 cm\(^{-1}\) (C–H stretching region) for PP and EPR, respectively. By acquiring spectra at various mirror velocities from samples consisting of a series of PP and EPR ratios, a PA calibration plot was devised to determine the amount of each component at various depths.

PAS has also been used to investigate the diffusion of monomers in concentrated polymers, along with thermal relaxation processes near the glass transition temperature for amorphous polymers. In this study, a mixture of ethanol (EtOH) and hydroxyl-terminated poly(dimethyl siloxane) were situated in a PA cell such that the IR probe light was mechanically blocked in order to determine the gas phase concentration of EtOH. The partition coefficient, \( J \), of the EtOH in the gas phase and sample, and the diffusion coefficient, \( D \), of the system were calculated by inspection of the \( \text{EtOH} \) band due to C–O stretching normal vibrations. Thermal relaxation processes were analyzed by using poly(butyl methacrylate) and poly(vinyl acetate) at various temperatures near the glass transition temperature. These studies indicated that molecular dynamics cause changes in specific heat near the glass transition temperature, which, in turn, have an affect on PA intensity.

Novel applications of CS PAS were illustrated in rheo-photo-acoustic (RPA) spectroscopy studies, where IR measurements were performed on a stretched polymer sample to monitor the static stress–strain response. For example, this method was used to determine diffusion rates of ethyl acetate (EtAc) in PVDF, which was shown to be a function of several variables including structural changes, polymer morphology, amount of applied strain, and EtAc concentration. Further examination of the same system using RPA spectroscopy allowed quantitative calculation of diffusion coefficients of EtAc in PVDF, which were shown to depend upon the fraction of amorphous phase.

Mongeau et al. presented one of the first methods to separate the PA bulk and surface signals using vectorial relationships (Figure 18). In this study, it was determined that signals originating from the surface, \( S \), and bulk, \( B \), can be calculated by setting the phase channel equal to one of these signals. The technique employed CS PAS methods, therefore an inherent weakness of this approach is a consequence of the thermal diffusion length wavenumber dependence. This ultimately results in a discrete collection angle for each wavenumber in order to collect the appropriate vector component.

One of the recent studies showed that it is possible to determine the work of adhesion using stress–strain experiments inside a PA cell. In the experimental set-up shown in Figure 19, substrate is elongated, and at the same time PA FTIR spectra are recorded. Interfacial forces responsible for the adhesion of coatings are
influenced by the nature and magnitude of the interactions between the coating and the substrate. When stresses are applied, these interactions are altered, resulting in potential energy changes within the neighboring layers of macromolecules forming an interfacial region, such as dispersive, repulsive, and inductive interactions illustrated in Figure 19. Therefore, vibrational energy and band intensities of the most outer species at the interface will change, which allows one to determine the work of adhesion.

4.3 Step-scan Photo-acoustic Spectroscopy Methods

The most recent developments in PAS resulted in S2 PAS, where the ability to acquire spectra at the same sampling depth for all wavenumbers makes this method most appealing.\(^{(114–118)}\) Similar to CS PAS, depth-profiling capabilities are possible, however in this case the modulation frequency is varied to obtain information from a specific depth. Studies performed by Palmer and Dittmar\(^{(66)}\) showed the utility of this technique by applying a series of modulation frequencies to various samples. Most notably, these experiments illustrated an S2 PAS method similar to Mongeau et al.\(^{(111)}\) where selective control of recording surface or bulk information is obtained by changing the experimental collection angle. For a PP sample surface treated with cobalt tetrakis(3,5-dimethylphenyl)porphyrin (CoTPP) and hexamethyldisilazane (HMDSiN) plasmas, it was determined that a greater amount of surface information was acquired at lower collection angles, whereas higher collection angles showed more PP contributions.

A more recent study used a similar depth-profiling approach by changing the collection angle to characterize fibers.\(^{(119)}\) In this study, a spectrometer frequency of 400 Hz was employed to determine absorbing layer depth of various polyamide bands due to the outer cuticle and inner cortex of a keratin fiber. The bands selected for characterization of the cuticle and cortex were the amide I band at 1650 cm\(^{-1}\) (CO stretching), and the 1540 cm\(^{-1}\) amide II band (CN stretch and NH deformation), respectively. It was determined that in order to calculate absorbing layer depth, a phase shift correction, which accounts for experimental conditions, such as sample and spectrometer characteristics, must first be subtracted from the experimental data.

4.4 Step-scan Photo-acoustic Spectroscopy Phase Analysis

An attribute unique to PAS in comparison to other FTIR techniques is the ability to extract additional sample information by performing PA phase analysis. Although this method was introduced in the 1970s, there is significant interest involving this technique,\(^{(120–122)}\) because it allows extraction of spectral information from layers underneath the surface with no interference from the top surface layers. One useful example illustrating this capability is shown in Figure 20, which illustrates a model of PUR/PP sandwiched polymer films on which phase
rotational analysis at different modulation frequencies was performed.\cite{123} Figure 21 illustrates a series of PA FTIR spectra recorded at specific modulation frequencies and it is quite clear that as the modulation frequency increases, more PUR is detected, as demonstrated by the appearance of the enhanced intensity of the 988 and 967 cm\(^{-1}\) bands. With this in mind one can choose desired modulation frequencies and collect information at two orthogonal detector channels referred to as in-phase (0\(^{\circ}\)) and in-quadrature (90\(^{\circ}\)). This represents conceptually a surface and a bulk signal, respectively, and Figure 22(a) and (b) illustrates this process conducted on PUR/PP layers. In this case the spectra were recorded at 732 and 23 Hz modulation frequencies. Since the bands at 998 and 997 cm\(^{-1}\) are attributed to the PUR layer, while the bands at 997 and 973 cm\(^{-1}\) are due to PP, their intensity changes will represent the contribution of each layer to the spectra. As seen, the \(I\) and \(Q\) spectra recorded at 732 Hz exhibit the presence of PUR and PP bands, indicating that the phase rotational analysis provides spectral information from PP (\(Q\) spectrum). However, when the modulation frequency is lower, indicating that the penetration depth will be higher, the same analysis results in the presence of the PP bands only. Thus, the entire spectral information comes from PP, and there is no interference from the top PUR layer.

One of the approaches to PA phase analysis was developed by Jiang et al.\cite{85,124} who calculated the surface temperature contributions for sublayer species with various thermal and optical properties. Experimental confirmation of this approach was obtained by determining a surface phase reference angle with a 60% carbon black-filled rubber elastomer, followed by determination of the experimental phase of a HMDSiN plasma-treated PP substrate, ethyl vinyl acetate on PP, and a CoTPP plasma on HMDSiN and PP at various frequencies. The differences between the phase measurements for bands
distinct to an absorbing layer were then calculated and compared to the theoretical values. It was shown that layers deeper within the sample have greater phase lags than shallow layers, in addition to the fact that phase depends on modulation frequency.

Another study used a similar phase difference approach with various plasma treated samples. However, in this case depth-profiling was performed by using the experimental phase angles acquired at 400 Hz to calculate the absorbing layer depth of a particular species, by subtracting phase angles of spatially different species. The authors concluded that obtaining phase angles from other modulation frequencies is unnecessary to acquire all spatial information, which is inconsistent with the prior theory.

A method to determine absorbing layer depth for samples with overlapping IR bands was performed by Jones and McClelland using vector analysis. In this study, PET films of known thickness were placed on a polycarbonate (PC) substrate, followed by the subsequent monitoring of the phase angles of the carbonyl C=O stretching bands at 1730 (PET) and 1778 cm\(^{-1}\) (PC). Similar to previous studies, the spectra were collected at a reference phase angle determined by a strongly absorbing sample, in addition to collecting data at one modulation frequency (400Hz) to correlate all absorbing layer depths. Phase analysis was performed using analytical trigonometric equations to extract PA signal phase and subsequent depth of a species with overlapping contributions. More importantly, this study experimentally showed PA magnitude as a function of phase angle.

Recent studies focused on investigating PET films of known thickness and determined discrepancies in using carbon black samples to determine phase reference angles. This conclusion was based solely on the fact that large phase errors occurred between carbon black reference angles from different manufacturers. Marginal errors resulted from an examination of PET with various thickness, therefore transparent spectral regions of PET were used to determine a collection angle. Similar to other studies, this study showed that for all specimens the reference angle displayed frequency dependence, which was attributed to the phase contribution from the experimental apparatus.

A promising development using the PA signal phase is displayed in two-dimensional IR correlation analysis. This method extends the uses of the I and Q spectra of S\(^2\) PAS even further to create a two-dimensional array showing depth correlation of various species, similar to the combined use of both PA phase and magnitude. An implementation of all phase analyses to various systems may enhance PA spatial resolution beyond the limits of most current surface sensitive techniques.

5 INFRARED AND RAMAN IMAGING

In analysis of coatings it is often essential to correlate surface morphology with molecular level information responsible for this morphology. For that reason IR and Raman microscopy and imaging are quite useful because they are capable of obtaining x–y direction information illustrated in Figure 2 and are capable of surface mapping. Principles of IR microscopy are the same as for ordinary optical microscopy, where a specimen is illuminated using a visible light in order to obtain a magnified image of the area of interest. Once the area for analysis is chosen and illuminated, the mode of operation is switched to IR light and the same area is illuminated by IR light, followed by collecting the IR spectrum. Figure 23 illustrates an example of IR mapping of a polymer latex surface. The spectra were collected from areas labeled A–E and indicate the presence of surfactant islands on the surface resulting from stratification across film thickness. Chemical imaging using the recently developed Stingray system by Bio-Rad
represents state-of-the-art imaging technology. Figure 24 illustrates Stingray images of 128 PUR films recorded in the transmission mode. As seen, nonhomogeneous cross-linking reactions occur, as demonstrated by changing NCO intensities.

Similar principles apply to Raman microscopy where a laser beam illuminates a designated area and inelastically scattered light is collected to obtain Raman or FT Raman spectra. The most recent approach to Raman microscopy involves Raman chemical imaging in which a laser is focused in such a way that wide illumination is obtained at the sample surface. The laser light is directed to a holographic notch filter optimized for oblique illumination placed in the optical path of an infinity-corrected microscope. Figure 25 shows a chemical imaging set-up in which reflected light propagates through an objective and is transmitted through a holographic notch filter that rejects light at the laser wavelength. A second notch filter is positioned after the first filter and provides additional rejection of the elastically scattered (Rayleigh) light. The Raman emission is filtered with a 9 cm\(^{-1}\) bandpass liquid crystal tunable filter (LCTF) constructed in the Evans split-element geometry. The LCTF is an electronically tunable filter capable of high fidelity Raman imaging and has been described in the literature.\(^{(129,130)}\) In a typical experiment the images are collected using a slow scan charge-coupled device from an approximately 20-µm square of 512 × 512 pixels. While Figure 25 is a schematic diagram of Raman chemical imaging, Figure 26 shows an image of an epoxy surface.
coatings, especially when nondestructive measurements are needed, and IR and Raman spectroscopy play a key role in surface depth profiling of coatings. Since both approaches or their variations do not require high vacuum environments, specimens are not altered. While ATR, RA, and PA FTIR techniques will continue to be utilized as powerful surface tools, Figure 27 illustrates three processes for obtaining surface information: optical imaging, spectroscopic analysis, and chemical imaging. The primary difference between optical imaging and combined with spectroscopic analysis is that the combination of both allows us to obtain visual representation of the analyzed area. In contrast, in chemical imaging the analyzed surface is represented by individual pixels that contain spectral information. Because of recent and anticipated future technological advances it is possible to combine imaging and spectroscopy into a new area called chemical imaging, and it will not be long before numerous techniques will be combined together to provide multi-measurement capabilities on a molecular level.

Coatings can be liquid or solid materials; they have been known and used from the time of early man and are of major importance for protecting and decorating the myriad of items in use today. These thin protective films are used to coat commercial and residential buildings (architectural coatings) and for many products in use today (industrial coatings). This article is concerned with the formation of coating films and the properties of these films. Static and dynamic mechanical properties, flexibility, toughness, adhesion, hardness, abrasion resistance, slip, chemical resistance, and stress within coatings are discussed and ways to investigate these characteristics are given. Some of the end-uses and the relationship of coating properties to the uses are detailed.

1 INTRODUCTION

The term “coating or coatings” is used to designate liquid or solid materials. A product that is to be applied to a substrate in a continuous or discontinuous film by one of many application methods is a liquid coating. After the liquid coating is dried by evaporative means or is cured (cross-linked) by oxidative, thermal, ultraviolet light or other method it is a solid coating film. This article will deal for the most part with solid coating films and the properties of liquid coating films can be found elsewhere in the encyclopedia. Coatings can be colorless or colored; they are thin, solid films that are transparent, translucent, or opaque in nature. The terms “coatings” and “paint” should be synonymous, but often coatings refer to industrial coatings such as those used on appliances, office furniture, paper, automobiles, beverage cans, etc. and paint refers to architectural coatings such as house paints, wall and ceiling paints, trim paints, etc. The materials used by artists are referred to as artists’ paints. While this is not a clear distinction, it is useful to be aware of a general differentiation in the terms and of the way they are used on a daily basis. Consider also that coatings are often referred to as finishes.

Paints can be defined as dispersions of pigments, optionally including fillers, in a fluid vehicle. The fluid vehicle comprises a liquid binder that will solidify during cure and, if necessary, a liquid carrier that serves as a viscosity reducing aid and will provide desirable application characteristics. The liquid carrier is lost to the local environment or recovered during the drying or curing process. The binder portion of the fluid vehicle is an oil, dissolved polymer, and, when appropriate, a cross-linking agent, or a dispersed polymer in latex or other dispersion form. The binder holds the pigment, filler particles, and miscellaneous formulating ingredients when it solidifies into a film on exposure to air or some other curing media. Varnish, a term that is often replaced by the term clear coating, is a clear or transparent solution that solidifies into a functional film. Lacquers are opaque and/or colored varnishes. Collectively or individually, paints, varnishes, and lacquers are termed coatings.

Coatings can be functional and/or decorative in nature. One need only to look at almost any surroundings to see how widely coatings are used. Many things that can be seen are coated with a decorative and/or a functional material. For example, within an office there might be walls and ceiling coated with a colored decorative paint; a desk coated with a clear, functional finish, which may be applied over a colored, decorative stain coating; alternatively the desk could be coated with a colored, opaque, functional and decorative coating; a floor coated in a manner similar to that of the desk with a functional and decorative coating; there may also be an aluminum beverage can coated on the outside with a decorative coating that serves as an advertising and identification medium and coated on the inside with a functional coating that protects the metal from the chemical nature of the can’s contents. In addition to the above, there may be...
many books, perhaps a newspaper, and other printed material. Some of these are printed on coated paper, and the printing in itself is a coating that is discontinuous in nature. The book jackets and some of the illustrations in the books are continuous-film coatings. Sheets of labels found in an office are coated with a pressure-sensitive adhesive. The list could go on, but it is readily apparent that we are surrounded by coatings.

Decorative coatings can be brilliant and bright to attract visual senses quickly; pastel and soft to provide a restful atmosphere; single color or multicolor to provide a variety of dramatic effects; glossy, semi-glossy, or matt to provide different mood effects or to affect cleanability; rough or smooth, and so on. Functional coatings often protect substrates – wood, metal, plastic, or other – from the ravages of nature, which often provide a hostile environment and can cause wear through rusting, erosion, light attack, etc. The protection provided by functional coatings saves natural resources and is friendly to the environment because it minimizes corrosion and other means of degradation, thus allowing a substrate to last for a much longer period than it would without protection. Such coatings could also protect an expensive part of an assembly that cannot be reached or is difficult to reach for repair, such as the role conformal coating plays in the electronics industry. Here the coatings protect printed circuit assemblies from the hostile environment found in outer space and sometimes within plants, laboratories, or living quarters. Pressure-sensitive adhesives applied to the back of heavily coated paper or polyester film form widely used functional label products of various designs.

Coatings can be divided into two broad groups: architectural coatings and industrial coatings. Architectural coatings are those used in decorating and protecting houses and other buildings. If the coatings are used on the portion of the building exposed to atmospheric conditions, they are termed exterior coatings. Such coatings are usually made from materials that are not light (radiation) sensitive or are stabilized against attack by radiation of different wavelengths. If they are used on the inner portions of the buildings, they are referred to as interior coatings; this group is further broken down into ceiling paints, wall paints, varnishes, masonry paints, and stains.

2 HISTORY

Early humans used plant extracts, tree saps, animal fats, berry juices, and metal oxides to create paints that were used to decorate and communicate by means of pictures, often on cave walls. Such pictures have remained well defined and vibrant for over 15,000 years. Early Egyptians coated dead bodies with bitumen and other materials in the mummification process (the word mummy is derived from the Persian word mumia, which means bitumen or pitch) and it is said that Noah’s ark was coated with pitch. About 2500 years ago, Egyptians developed clear varnishes by heating amber and vegetable oils; colored coatings or lacquers were made by adding ground minerals such as malachite, azurite, and iron compounds to the clear varnishes. Early Romans developed the method of fresco painting in which paints composed of pigments, fillers, and carrier vehicles were applied to wet plaster for interior surface coatings and paintings. Ancient Hebrews used milk-based paints for decorating walls and ceilings. Over 3000 years ago, the Japanese developed lacquers based on sap from the varnish tree (the Japanese sumac, Rhus verniciflua). In colonial days, water-slacked lime – whitewash – was extensively used for a variety of coating purposes. Later whitewash was modified with milk and protein-based materials to improve durability and adhesion. This was followed by the addition of pigments, fillers such as clay, and whiting to provide a variety of products with improved aesthetic appeal and economics. Finally, the lime was replaced with milk phosphoproteins, and whitewash became casein paint, a forerunner of today’s architectural paints.

Although paints were used and modified in such ways for centuries, it was not until the Industrial Revolution (1700–1950) that the paint and coating industry took on far-reaching importance. This historical period resulted in the production of a multitude of bridges, factories, manufacturing machinery, and allied equipment, as well as other items; all of these needed to be coated to provide protection from hostile natural and derived environments. Protection had to be provided from moisture, salt water, barnacles, mildew, mold, wind, rain, hail, heat and cold, sunlight, sulfurous fumes from coal fired furnaces, etc. This protection was provided by coatings that extended the lifetime of the world’s infrastructure, the manufacturing facilities, and the ever increasing number of manufactured items. Today, the same items plus a myriad of other items – packaging, cars, trucks, trains, boats, furniture, beverage can liners, wallpaper, etc. – that grew out of the ever expanding manufacturing base are coated with a protective and very often aesthetically pleasing film that is usually thinner than a sheet of writing paper. If it were not for paint and coatings, our world would certainly be a dull, corroding place in which to live.

3 ARCHITECTURAL COATINGS

Architectural coatings are those coatings used on interior and/or exterior surfaces such as those found in or
on commercial, institutional, industrial, and residential buildings as well as on various structures such as bridges. The surfaces coated are wood, metal, composition, plaster and wallboard, plastic, or masonry. The coatings may be latex, alkyd, oil, solvent borne, and so on, and they are applied by brushing, spraying, rolling, as well as other methods. Gloss is an important optical characteristic of these coatings and varies from low to high depending on any particular end-use. These coatings are often termed trade sales paints, because they are usually purchased by consumers who will apply them on-site under ambient conditions.

Standard methods are available to test the characteristics of architectural coatings. Abrasion, dry and wet adhesion, flexibility, chemical resistance, block resistance, print resistance, and cleanability are important properties. Abrasion resistance, adhesion, and flexibility are discussed elsewhere in this article. Mechanical properties of architectural coatings are not usually directly measured, but rather such properties manifest themselves in the results of an end-use-related test. Testing of architectural coatings and industrial coatings is often a measure of a complex interaction of various coating physical characteristics. For example, washability and related characteristics of a wall coating requires the coating to be chemically resistant to water and detergent and to be sufficiently strong to withstand a scrubbing action that applies tensile and shear stresses to the coating as its hardness, adhesion, cohesion, and abrasion resistance are brought into play.

Ease of application and aesthetic characteristics are more important than mechanical characteristics for interior coatings. However, mechanical and other physical properties are important to exterior architectural coatings that are subjected to outdoor exposure. Exterior coatings are exposed to heat and associated temperature changes, moisture, oxygen, and sunlight. These factors individually or in concert contribute to coating failure. Temperature changes alter properties and can result in significant alternating strains, along with concomitant stresses, being placed on the coating–substrate matrix. This, coupled with the effects of exposure to relatively high temperatures, results in cracking, checking, embrittlement, and peeling. Moisture can cause blistering, erosion, loss of adhesion, and mildew. Oxygen can cause surface degradation and eventually internal degradation, resulting in embrittlement, cracking, and crazing. Sunlight and, in particular, the ultraviolet light component of sunlight can cause surface chalking and loss of gloss, degradation, and embrittlement, with accompanying cracking and discoloration.

Effects of outdoor exposure are often measured with test devices that attempt to simulate and accelerate changes that would be encountered in the environment. Accelerated exposure test results are often difficult to reproduce and may not correlate with actual or natural exposure testing. However, such testing is widely used because natural weathering can take years to effect changes, and the accelerated tests do give a good indication of coatings that will fail early. They are particularly important for comparison purposes, for new product development, and to improve the durability of existing products.

Natural weathering is a true measure of the ravages of nature; however, it is reproducible only if properly planned, conducted, inspected, and reported. Natural weathering tests are not carried out by merely placing a test specimen outdoors and letting sunlight, rain, and so on fall on it. Rather, the testing is carried out at selected sites with the exposed specimens set at a particular angle. Conditions such as these affect the four major factors listed above and allow other factors such as humidity or lack of it, biodegradation, and pollution to be brought into the testing scheme. The synergistic interaction of these factors, which will vary with exposure site, determines how a coating’s failure through outdoor exposure takes place. The variation of solar energy radiation dosage with season and with the angle of the test specimen to the sun is an important variable to be considered when reproducible test results are expected. The closer the test conditions simulate the actual use conditions, the more accurate will be the prediction of long-term results.

### 4 INDUSTRIAL COATINGS

Industrial coatings are coatings applied to factory-manufactured products. These include, but are not limited to, transportation coatings (those coatings applied to aircraft, appliances, automobiles, buses, recreational vehicles, trucks, and trains) beverage-can and spray-can coatings, packaging items, business machine and office furniture coatings, wood cabinet and furniture coatings, pipeline coatings, printed circuit board and assembly coatings, sign coatings, marine coatings, and masonry coatings.

#### 4.1 Film Formation

Coating films are formed from either thermoplastic (soluble) or thermoset (insoluble) polymers combined with other ingredients, including, if desired, but not limited to, pigments, fillers, colorants, plasticizers, surfactants, solvents, catalysts, or initiators. Thermoset coatings are formed from initially soluble ingredients that react and undergo a change termed cross-linking as a consequence of an energy input.
When thermoplastic polymers are dissolved in a solvent, films are formed by evaporation of the solvent under ambient conditions or in the presence of controlled heating. Since physical characteristics of the final coating are dependent on the polymer’s properties, polymers of high or relatively high molecular weight are used. The high molecular weight limits the amount of polymer that can be dissolved because the viscosity of the final system must be sufficiently low to allow the coating to be applied by brush, spray, roll-coater, etc. Polymers that are used to form coating films include nitrocellulose, cellulose acetate butyrate, vinyl chloride/vinyl acetate copolymers and terpolymers, poly(vinyl acetate), and poly(methyl methacrylate). Coatings such as these are easily removable with a solvent or marred by a plasticizing compound; in addition particular liquids can attack the coating, for example water or alcohol can cause a ring on nitrocellulose-coated furniture.

Thermoset coatings are produced when multifunctional low-molecular-weight polymers or oligomers are reacted with a multifunctional cross-linking compound that contains appropriate functionality. If a solvent is present, it is removed by evaporation to form a film, which is then heated to effect reaction between the different functionalities in the presence of (or without) a catalyst. If the cross-linking reaction is between hydroxyl-containing and isocyanate-containing or epoxide-containing compounds, for example, the reaction proceeds by an addition process without emissions to form either urethane linkages or ether linkages (Scheme 1).

If the reaction is between a hydroxyl-containing compound and, for example, a methoxymelamine, material is lost by emission of a volatile by-product, in this case methanol (Scheme 2).

In addition to forming films by evaporation of solvent from solutions of polymers and oligomers, films can be formed from aqueous and non-aqueous dispersions, organosols, plastisols, electrodeposition, powders, and radiation-activated systems. The American Society for Testing and Materials (ASTM) and other organizations have a variety of test methods for determining various aspects of film formation and the films formed. These include detailed procedures for preparing and testing organic films, for drying, curing, and formation of films, for determination of minimum film formation and coalescence temperatures of aqueous dispersions, for permeability, for block resistance, and for numerous other particular physical factors. A number of the physical property tests are briefly described below.

The degree of cure or solvent resistance of films, particularly thermoset coatings, is often determined by means of a solvent rubbing procedure that is formalized for zinc-rich, ethyl silicate coatings. A gauze cloth is made into a pad and saturated with a solvent such as methyl ethyl ketone or acetone. Then, using thumb pressure, the solvent-wet pad is rubbed back and forth over the coating. Although the test is said to be imprecise because of variability in thumb pressure from operator to operator, it does provide quick, useful results, particularly on a comparative basis. Other tests can be found to determine solvent resistance.

4.2 Mechanical Properties

Mechanical properties such as tensile strength, elongation, and toughness and related parameters are important characteristics of coatings. Outdoor coatings must withstand the rigors of the tensile and compressive forces that occur and cause expansion and compression during each day and with the changing seasons as the temperature changes. Hail and sleet challenge the toughness of coatings. The effects of temperature on coatings for wood substrates are further complicated by the differences in hardness, chemical composition, and expansion coefficients of spring wood and summer wood. Obviously, these changes occur many, many times over the course of a number of years. Many coatings are applied to a substrate before forming operations are carried out. Consider the metal white caps that are applied to a variety of packaged foodstuffs. The caps are formed after the white coating is applied to sheet steel. The coated metal is subjected to severe tensile and shear forces during the strong bending and twisting operations required to form the cap. The coating–steel composite must have excellent adhesion, strength, and toughness to withstand the torturous operation. Three-piece beverage cans undergo severe bending and twisting when the can ends are combined with the can body in a flanging operation. The same is true

\[
\text{Scheme 1}
\]

\[
\text{Scheme 2}
\]
when the lid is attached to a two-piece can. In addition, when the filled cans are transported by truck, the coated, filled can is again subjected to twisting and flexing during handling and with each bump and turn in the road during transportation. The severity of these operations is such that pin holes and failure can develop in the container and cause product loss as well as potential liability.

Tensile properties are those characteristics that a material exhibits when a uniaxial force \( F \) is applied to a specimen of length \( L_0 \) and cross-sectional area \( A \), as depicted in Figure 1. Under no-load conditions, the specimen is at rest. When the force is applied, the specimen experiences a tensile stress, \( \sigma \), that is equal to the applied force per unit area and an elongation to a final length, \( L \), involving a tensile strain, \( \varepsilon \), which is given by change in length per unit length or \((L - L_0)/L_0\). In the region where stress is directly proportional to strain, a tensile modulus, \( E \), can be defined as the slope of the stress–strain relationship as shown in Equations (1) and (2). (Similar expressions can be defined for shear and bulk deformation conditions.)

\[
E = \frac{\text{Tensile stress}}{\text{Force per unit area}} = \frac{\text{Change in length per unit length}}{\text{Tensile strain}}
\]

\[
E = \frac{F}{A} \cdot \frac{\Delta L}{L_0} = \frac{\sigma}{\varepsilon}
\]

However, polymers and coatings actually have no measurable region where stress is proportional to strain because polymer molecules can flow under an applied force. That is, polymers are not elastic in nature; rather they are viscoelastic and slowly flow when placed under conditions of loading. The modulus of viscoelastic materials has a storage or completely recoverable elastic component \( (E') \) and a viscous or loss component \( (E'') \) that is not recoverable and the energy of which is lost through viscous heating during the stressing process. To circumvent this problem, when measured under static conditions, the value of \( E \) is calculated by measuring the stress at some stated, fixed strain, usually 1% or less, and dividing it by the strain. Such a measured value of \( E \) is denoted as the secant modulus\( (E_{\sec}) \) measured at the selected strain.

Dynamic mechanical analysis (DMA) is a technique that enables the two components \( E' \) and \( E'' \), which together are known as the complex tensile modulus, \( E^* \), to be distinguished and measured.\( ^{34,35,36} \) In DMA, the stress or strain described in Figure 1 is applied to the specimen in an oscillatory manner that is usually described as being sinusoidal in nature, though the exact nature of the deformation depends on the particular instrument used for the measurements. A sample is held under sufficient tension that it is not limp at the lowest applied oscillatory strain. Although the impressed wave motion is the same, say sinusoidal, for the stress and the strain, because of the material’s viscoelastic nature these properties are out of phase by an amount or angle, \( \delta \), the phase lag. For an ideal elastic material, \( \delta \) is zero and the stress and strain are in phase. For a Newtonian liquid, if it could be so tested, \( \delta \) would be 90°. For viscoelastic materials, \( \delta \) is between 0 and 90°. These components of the modulus can be represented as two vectors that are 90° out of phase with each other, as described in Figure 2.

Equations (3–6) describe the stress wave as two waves, one in phase with the strain (the elastic response) and the other 90° out of phase with the strain (the viscous response).

\[
\text{Storage modulus} \quad E' = \frac{\sigma_1 \cos \delta}{\varepsilon}
\]

\[
\text{Loss modulus} \quad E'' = \frac{\sigma_1 \sin \delta}{\varepsilon}
\]

\[
\text{Complex modulus} \quad E^* = \sqrt{E'^2 + E''^2}
\]

\[
\text{Loss tangent} \quad \tan \delta = \frac{E''}{E'} = \frac{\sigma_1 \sin \delta}{\sigma_1 \cos \delta}
\]

The complex tensile modulus, \( E^* \), or the one that is actually sensed, can be calculated from the components, \( E' \) and \( E'' \), by the Pythagorean theorem. The ratio of the viscous response to the storage response is equal to the}

\[\tan \delta = \frac{E''}{E'} \]

\[\frac{E''}{E'} \]

**Figure 1** A specimen at rest and in a tensile-loaded condition.

**Figure 2** Vector representation of the components, \( E' \) and \( E'' \), of the complex shear modulus, \( E^* \), and the phase angle, \( \delta \).
tangent of the out-of-phase angle and is known as the loss tangent. When these parameters are measured as a function of temperature, the loss modulus and the loss tangent exhibit maxima at the glass transition temperature, \( T_g \), and at other temperatures if there are other secondary loss mechanisms. Below \( T_g \), materials are glass-like in nature – hard and brittle – and above \( T_g \) they are soft and flexible in nature. If the system is cross-linked, above \( T_g \) the material will exhibit an extensive rubbery nature.

To visualize the storage and loss components of a material, consider a rubber ball that is dropped from some height onto a hard, elastic surface. The ball will bounce up and down with a decreasing height as each succeeding bounce takes place until it is finally at rest. The elastic nature of the ball causes it to try and return to the release point by means of stored energy, but the viscous nature of the ball results in it losing energy as heat to the surroundings; consequently, the ball reaches a height somewhat less than the original height. The motion is gradually damped until finally the ball ceases to bounce. One readily knows that a markedly different result is obtained if this experiment is performed on a summer day than on a winter day. Actually one can measure important physical properties of materials by this technique, but a number of more practical methods than this one exist.\(^{36}\)

### 4.3 Flexibility and Toughness

Flexibility is the ability of a coating to be bent or flexed in forming operations without cracking, losing adhesion, or failing in some other manner. Toughness is the ability of a coating to withstand large stress forces imposed over a short time without cracking, rupturing, shattering, or tearing.\(^{37}\) Coatings must properly perform during manufacturing operations, during use, and often during misuse. To do this, they must have sufficient flexibility and toughness to withstand failure when subjected to bending and twisting, as is encountered in forming operations, to expansion and shrinking during temperature changes, and to mechanical abuse.

Flexibility is usually measured by a mandrel bend test\(^{33}\) or a T-bend test.\(^{35}\) The mandrel bend test involves bending a coated substrate, usually sheet metal or rubber-type materials, over either a conical mandrel or over cylindrical mandrels of various diameters. The standard, smooth-steel, conical mandrel has a length of 203 mm (8 in) and a diameter of 3 mm (0.125 in) at one end and 38 mm (1.5 in) at the other end. The coated substrate, coating side up, is bent around the mandrel with a lever device and the extent of cracking, if it exists, is determined. The distance from the small end of the mandrel to the crack is determined visually and can be used graphically to determine the percent elongation. (However, there is no indication in the test method that elongation determined from tensile studies will yield a value related to the cracking-failure point.) The mandrel diameter at the point where cracking ceases is reported as the resistance to cracking resistance or flexibility.

The cylindrical mandrel test is a pass/fail test that involves placing the coated substrate over a mandrel, coating side up, and bending the specimen about 180° around the mandrel by hand at a uniform velocity in a specified time. Usually six mandrels having diameters ranging from 25 mm (1.0 in) to 3.2 mm (0.125 in) are used. The panel is bent over the largest diameter mandrel and then immediately examined for cracking. If none occurs, the next smaller mandrel is used and so on until failure occurs or the smallest diameter mandrel has been passed. The smallest diameter at which cracking does not occur is reported. The test can be used to calculate coating elongation.

The T-bend test involves placing a coated metal panel with a 50 mm (2 in) minimum width in a smooth jaw bench vise and holding it firmly.\(^{38}\) The panel must be sufficiently long that the needed number of bends can be made, i.e. about 150 mm (6 in). Then the panel is bent 90° with the coating on the outside of the bend, removed, and further bent by hand until the bent end can be inserted in the vise; the vise is tightened to complete the 180° bend. The apex end of the bend should be as flat as possible. This is termed a 0T (zero-T) bend. The bend is then examined with a 5 to 10 power magnifier for cracks and pressure-sensitive tape is applied and removed to determine if coating can be picked off. The process is then repeated by placing the bent end in the vise and bending through 180° around the 0T bend. This forms the 1T bend. This is continued for 2T, 3T, etc. bends. The lowest T bend at which no cracks are visible and there is no pick off of coating is the value reported. Note that the radius of curvature of the bend increases with each succeeding bend and coating elongation required to make the bend decreases with each succeeding bend.

Flexibility of pipeline coatings that are to be subjected to short-radius bends is determined by bending the coated pipe around a designed, variable-radius mandrel to produce a range of short-radius bends.\(^{39}\) Coating failure is apparent by visual and/or electrical inspection of cracking or loss of adhesion.

Toughness can be defined as the ability of a coating to withstand an impact without cracking or breaking. It is dependent on the nature of the polymer or polymers used in the coating and on adhesion. Impact resistance, which is related to formability, can be measured by dropping a weight from various heights through a guide tube onto an indenter that rests on the surface of the coated substrate.\(^{40}\) The test can be made on the coated side (face impact) and/or the uncoated side (reverse impact).
of the coated substrate. Cracking or other failure is noted on or around the dimple caused by the indenter. The cited ASTM test gives three procedures for ascertaining failure: visual inspection, application of an acidified copper sulfate solution, and use of a pin hole detector. Several impacts are made at different impact values and at the same impact value. The value where the force required changes the result from mainly passing to failing is the test end-point. The result at this point is reported as kilogram-meters (inch-pounds) impact resistance.

A wedge bend device is used to determine impact resistance and formability of metal strips that have been factory coated by a roll coating or other application technique.\(^{(41)}\) Coated strips are bent 170–180° over a 3.2-mm (0.125 in) cylindrical mandrel that is attached to the impact platform. A 1.82-kg (4 lb) guided rod with a flat end is then dropped onto the test specimen. Variation in the height of drop allows the force needed to crack the coating to be measured. A test that involves high-pressure pressing of an indenter ball into a zinc-rich primer-coated metal substrate tests the formability of the coated metal.\(^{(42)}\) Formability tests that ascertain the flexibility and impact resistance of coatings by stamping a die into coated metal exist.\(^{(37)}\)

The impact resistance of pipeline coatings is determined by a limestone drop test,\(^{(43)}\) a falling weight test,\(^{(44)}\) and a penetration resistance test.\(^{(45)}\) The limestone drop test involves dropping weighed amounts of a particular type of limestone through a chute onto a coated pipe. The number of drops required to penetrate the coating by either visual or electrical inspection is reported as the impact resistance. The falling weight test is similar to that described above except special pipe-holding devices and impactor surface characteristics are involved. Coating breaks or penetrations are detected by measurement of electrical resistance changes; the impact resistance is the amount of energy required to cause a break. The penetration resistance test involves applying a blunt rod loaded with a dead weight to a coated steel pipe. The depth or rate of penetration of the rod into the coating is measured as a function of time. This and any failure (cracking or other penetration) are reported.

### 4.4 Adhesion

The importance of adhesion, the ability of a coating to resist removal from the surface to which it is applied, is self evident.\(^{(46)}\) Such adhesion can be between substrate and coating, between a primer coating and a top coating, between coatings applied to an existing coating, etc. In addition, the coating must adhere under various weathering and cleaning, usually aqueous, conditions. The adhesion can be between the same – in a chemical sense – materials or between a broad variety of materials including plastics, wood and other cellulosics, metals, ceramics, etc. There are two aspects involved in adhesion: “basic” adhesion, which is the combination of all intermolecular and interfacial forces, and “practical” adhesion, which is the work needed to disrupt the adhering combination. Practical adhesion is almost always the quantity measured in the coating industry.

The most common method of testing coating adhesion involves applying an adhesive tape to the coating, which is either uncut or cut in some manner, and then removing the tape under specified conditions. The cut surface is observed and the degree to which the coating is removed is compared against standards. The test is considered simple to perform and low in cost. A widely used test method for coatings on metallic substrates\(^{(47)}\) involves making an X-cut in the film (method A) or making a lattice cut with a device that makes six or eleven cuts in each direction (method B) with each of the cuts made through the film to the substrate. A transparent, pressure-sensitive tape is applied to the cut area and removed in a prescribed manner. The coating is then visually examined and rated on a zero to five comparison scale. On this scale five indicates no removal and zero indicates greater than 65% removal from the scored area, with various descriptions for the values between the extremes. Method A is meant to be used on the job and method B is meant for use in the laboratory. The test and results are qualitative in nature, and the results are considered reproducible within one unit when the substrate is metal. On plastic substrates, reproducibility is poor since the test is not designed for relatively soft substrates that are usually coated with brittle coatings.

Adhesion of coatings to flat substrates can be determined by pushing the panel beneath a rounded stylus on a balance-beam device that is increasingly loaded until the coating is removed.\(^{(48)}\) This scrape adhesion test is used to differentiate the degree of adhesion to substrates. It provides relative rating values for coatings with considerably different degrees of adhesion.

The pull-off strength\(^{(49)}\) or adhesion of a coating is measured by applying an increasing tensile force perpendicular to the coating surface until a plug of material is detached. Alternatively, this test can be a pass or fail test if a prescribed stress is applied and it is determined if the surface remains intact under this stress. The tests are carried out with a portable device with a loading fixture that is secured to the coating surface with an adhesive. The adhesive is either a two-part epoxide or acrylic system. The fixture is aligned normal to the surface, and the tensile stress is applied in a slow (less than 1 MPa s\(^{-1}\), 150 psi s\(^{-1}\)) continuous manner until a plug of material is removed. The force attained at failure or at maximum force applied is reported. In addition, the plug is examined to determine the percentage adhesive and
cohesive failures, and the interfaces and layers involved in failure are reported.

4.5 Hardness

Coating hardness is the ability to resist permanent indentation, scratching, cutting, and penetration by a hard object. Different methods of evaluating hardness yield different results because they measure different qualities of the material. There is no absolute scale and each method has its own scale of defined hardness.

Determining hardness by gouging or scratching the coating with drawing leads or wood pencils of different hardness (from 6B to 6H) is simple and inexpensive; it is widely used in laboratory development work and production control testing. To conduct the test, the pencil is sharpened with a draftsman-type sharpener. The sharpened lead point is then held at a 90° angle to horizontal on No. 400 grit abrasive paper and rubbed until a smooth, flat, circular cross-section is obtained. To carry out the test, the coated panel is firmly held on a level surface and the hardest, sharpened pencil is held on the coating at a 45° angle. The pencil is then pushed away from the operator while using sufficient downward pressure to either cut through (gouge) or scratch the film or to crumple the edge of the lead. This procedure is repeated with softer and softer leads until a pencil is found that will not cut through or scratch the coating. The gouge hardness is reported as the hardest pencil that will leave the coating uncut for a push stroke of at least 3 mm (0.125 in). The scratch hardness is reported as the hardest pencil that will not scratch the coating. Because of the nature of this test, it is operator dependent and results may vary between different operators and laboratories.

Indentation hardness of coatings is determined with sophisticated devices that determine the resistance to penetration by an indenter. Knoop indentation hardness (method A) is determined by bringing a pyramidal diamond indenter into contact with the coating and then applying a selected load to the indenter and maintaining the load for 18 ± 0.5 s. After this time, the indenter is withdrawn. The Knoop device is equipped with a microscope that has a movable micrometer stage; immediately after the indenter is withdrawn, the microscope is adjusted and focused so that the indentation is in the field of the microscope. With the indentation sharply focused, the length of the long indentation diagonal is determined. The indentation length is converted into Knoop hardness numbers (KHN) with tables supplied by the instrument manufacturer. If the tables are not available, KHN hardness numbers can be calculated.

Pfund indentation hardness (method B) is determined with a device equipped with a microscope that will apply a 1.0-kg (2.2 lb) load to a hemispherical (3.18 mm, 0.125 in radius) transparent quartz or sapphire indenter that is in contact with the coating surface. The load is applied for 60 s; after that time, with the loaded indenter still in place, the diameter of the circular impression is rapidly measured. An instrument constant (1.27) is then divided by the square of the indentation diameter in millimeters to obtain the Pfund hardness numbers (PHN).

Numerous other methods exist that determine hardness by scraping and indenting as well as by marring and abrasion. In addition, hardness can be measured with pendulum damping devices and rocker devices. The three methods described above are in common usage.

4.6 Abrasion

Abrasion resistance is the ability of a coating to resist having its original appearance and structure altered when it is subjected to the influence of erosion, rubbing, scraping, or other ablative action. Both temperature and environment can have an effect on abrasion resistance, but the relationship between these factors and interrelated mechanical properties is not simple. For example, hardness and modulus increase with decreasing temperature, and this may be detrimental to abrasion resistance if the coating loses flexibility or toughness. Increases in humidity around an object or subjecting an object to a moist environment as in washing a wall can soften a coating and alter its resistance to abrasion. Other factors that can have an effect on abrasion resistance include toughness, strength, and other mechanical properties. Because of the complex interrelationship between characteristics that affect abrasion resistance, it is important that the test method subjects test specimens to conditions that are similar to those encountered in actual use.

Many, it not almost all, coated items are subjected to some sort of ablative action, and such action can cause marring and/or wear. These items include appliances, automobiles and other transportation equipment, beverage cans, business machines, farm equipment, floors, furniture, highways (traffic paints), interior and exterior structural walls, and so on. The actions include: wind, rain, hail, and other natural periodic actions; wear that can be relatively continuous, such as automobile traffic or walking; polishing or other rubbing of furniture or an automobile with a harsh fabric; or accidental contact of a coated surface with a button, a toy, or a similar object. An example of rubbing effects caused by similar objects rubbing against each other are those that are encountered when beverage cans rub against each other in a multipack during shipping and handling.

Abrasion resistance of coatings applied to flat, rigid surfaces can be measured by rotating the coating against an abrasive-filled, weighted wheel. The results are reported as the number of cycles to remove a unit amount of coating.
of coating (wear cycles per 25.4 µm), as the loss in weight per cycle multiplied by 1000 (wear index), or as the weight loss determined at a specific number of cycles (weight loss). Although this test method is fairly simple to carry out, reproducibility is poor. It is recommended that results be limited to testing in only one laboratory when numerical values are to be used. Agreement of results between laboratories is markedly improved if different coatings are merely ranked rather than trying to compare numerical values.

Coatings on non-planar surfaces such as those found on pipelines are tested for abrasion resistance by placing the externally coated pipe through a specially designed steel drum apparatus and eroding it with an aqueous, abrasive slurry contained in the horizontally revolving drum. The specimens are electrically insulated from contact with the drum. The test is applicable to all types of electrical insulating coating including thermoplastic and thermoset coatings and bituminous materials. Measurement of electrical resistance changes between the pipe and the drum as the coating erodes indicates the coating abrasion resistance. Because of electrical requirements, metallic protective coatings such as zinc are not tested by this method. However, such coatings and others designed to function as electrical barriers are tested for cathodic disbonding by other tests.

Painted interior house walls are soiled near doorways, windows, play areas, cooking areas, etc. Such soiled areas and often the entire walls are cleaned by repeated scrubblings, and during the scrubbing the paint is subjected to corrosion. The relative erosion resistance of interior, flat wall paints to wet scrubbing can be determined by applying the paint to particular black plastic panels and scrubbing with a nylon bristle brush that is wet with an aqueous, detergent-based scrub medium. The wet brush is driven in one direction across the coated surface; after each set of 400 cycles the brush is removed, the scrub medium is replenished, and the brush is replaced. This procedure is repeated until the paint film has been removed. The number of cycles to failure is reported. The test is designed for freshly painted surfaces rather than aged surfaces. The degree of erosion of exterior paints, which occurs mainly by chalking, can be determined by comparison of the surface with pictorial standards. Pictorial comparisons are also used to evaluate the wear resistance of traffic paints.

Abrasion resistance is also determined by air-blasting silicon carbide grains at the coated panel at a 45 g min⁻¹ flow rate. The abating is continued until the coating is worn through. At this point, the blasting is terminated, and the amount of ablative used is determined. The abrasion resistance is determined as the grams of ablative used per 25.4-µm film thickness. A similar test involves dropping a silica or silicon carbide abrasive through a guide tube from a specified height onto a coated planar surface. Silica (sand) is a milder abrasive than silicon carbide and the slower rate of abrasion it causes can be useful in discriminating between different coatings. Basically this test differs from the previous test in that the ablative contacts the coating under a gravity flow rate rather than an air-forced flow rate. The abrasion resistance is determined as the kilograms of ablative used per 25.4-µm film thickness.

4.7 Slip

Usually slip, meaning the opposite of traction or clinging, is not an inherent property of coatings unless one is discussing the tetrafluoroethylene polymers and copolymers. Coatings are said to have good slip when they have a low coefficient of friction and poor slip when they have a high coefficient of friction. Slip indicates the ease with which two contacting surfaces can move by each other. Coatings are said to have slip when they have a tack-free surface and behave as if they were lubricated.

Slip is an important characteristic of coated objects for it is the property that allows coated materials to slide by one another in forming operations, during filling, handling and shipping, as well as in other manufacturing and use operations. However, it is worth pointing out that the surface can be too slippery, that is have too low a coefficient of friction. Imagine a beverage can with a surface so slippery that it could not easily be held in a person’s hand. Also, a low coefficient of friction can be an undesirable characteristic in floor coatings, since people walking on the surface could slip and fall or vehicles could slide and cause damage or harm. Gymnasium floors, porch and deck floors, concrete work-area floors, and kitchen floors are areas where this is of particular concern.

Slip can be imparted to films by incorporating a compound into a coating formulation that is incompatible with the dried or cured coating; it will then exude to the surface of the coating. A way of imparting slip to flat, coated metal sheets is to spray lightly a very low-volatility lubricant onto the coating just after the coating is cured and prior to stacking for the next manufacturing operation. Compounds such as wax esters, fatty esters, alkanolamides, metallic stearates, waxes, and silicones are used to decrease frictional resistance or to control slip.

Slip is determined by measuring the frictional properties of coatings. Friction is the force between surfaces that opposes imposed sliding motion. It is the characteristic that determines the resistance to slip or the magnitude of slip.

In one method, the static friction of coatings is determined by an inclined plane sliding test or a horizontal pull test. The inclined plane test employs one or more weighted sleds that are individually placed on the coated
surface, which is fixed to a flat, movable surface. The movable surface is then inclined from the horizontal at a rate of $1.5 \pm 0.5\, \text{s}^{-1}$ until the sled begins to slide down the inclined coating surface. The tangent of the angle of inclination at this point is reported as the static friction. The horizontal pull test has a weighted sled placed on a specimen that is fixed to a flat, horizontal base. The sled is then pulled across the specimen with a mechanical power unit, and the force required to start the sled moving is determined. This force divided by the mass of the sled is reported as the static friction. Static friction determined by this method is useful for ascertaining the slipperiness of floor polishes, the slip resistance of footwear on floor tiles and floor coatings, the appropriateness of coatings for the exterior of cans, etc. The measurements are also useful to determine the effect of coating additives or spray lubricants on the slipperiness of coatings. A number of methods for determining friction can be found in the literature.\(^{66}\)

### 4.8 Stress in Coatings

Stresses can develop within coatings during film formation, through temperature changes, and through relative humidity (RH) changes.\(^{15}\) These internal stresses have an effect on coating degradation. They affect adhesion and/or cohesion and have an effect on delamination and cracking. Thermoset coatings have higher internal stresses than coatings that do not involve cross-linking compounds, such as lacquers and alkyds.

Although internal stresses can have a detrimental effect on adhesion, they originate through the process of adhesion. This seeming paradox can be readily understood if the following is considered. To protect a substrate adequately, good adhesion between the substrate and coating is required. However, adhesion causes immobility of the coating at and near this interfacial area, which, in turn, does not allow the coating to move in a normal manner, for example when the temperature changes.

When a solid coating film forms, a liquid is changed into a solid. While the film is liquid, the coating is mobile and volume contraction can take place with no stress development. As a solid coating film forms, in almost every instance contraction continues to take place but is restricted by adhesion. As a result of this restriction, tensile stresses develop within the coating. However, as soon as stress develops, the molecules seek to relieve the stress and a relaxation process begins. Therefore, as film development continues, stresses within the film can increase, decrease, or remain constant depending on the rate of stress development and of stress relaxation. It should be noted that stress development begins when the $T_g$ of the changing system is reached. In the case of a coating that is formed from a solution of polymer, this is at the point where the $T_g$ of the solvent/polymer solution is equal to the experimental temperature.

If it is assumed that the internal stress is in a plane parallel to the substrate and is isotropic in nature, the internal strain $\varepsilon_i$ can be described by Equation (7):

$$\varepsilon_i = \frac{V_s - V_t}{3V_s}$$  \hspace{1cm} (7)

where $V_s$ is the coating volume at the solidification point and $V_t$ is the coating volume at time $t$ after solidification. It is readily apparent that, as the volume decreases as a function of time during final film formation, the internal strain and, therefore, the internal stress increase.

Changes in temperature will cause the dimensions of a coating/substrate combination to change. Since the expansion coefficients of the coating, $\alpha_{c,T}$, and the substrate, $\alpha_{s,T}$, are almost always different, an internal strain, $\varepsilon_T$, is set up. This is described by Equation (8).

$$\varepsilon_T = (\alpha_{c,T} - \alpha_{s,T}) \Delta T$$ \hspace{1cm} (8)

Since absorption and desorption of water can cause similar changes in dimensions of the coating, $\alpha_{c,RH}$, and the substrate, $\alpha_{s,RH}$, Equation (9) similarly expresses the internal strain that is caused by RH changes.

$$\varepsilon_{RH} = (\alpha_{c,RH} - \alpha_{s,RH}) \Delta RH$$ \hspace{1cm} (9)

These stresses act together and may augment each other and be very important or they may negate each other and be small and relatively unimportant (Equation 10).

$$\sigma_{(total)} = \sigma_i \pm \sigma_T \pm \sigma_{RH}$$ \hspace{1cm} (10)

The component $\sigma_i$ is always positive, but the contributions from temperature and RH effects can be positive or negative. Positive effects occur in coatings that tend to contract and set up internal tensile stresses. Negative effects occur in coatings that tend to expand and set up compressive stresses. A dry, cold winter day will involve low temperatures and low RH, with high resultant internal tensile stresses. Conversely, a humid, summer day will involve high temperatures and RH, with resultant high internal compressive stresses.

There are a number of ways\(^{15}\) to measure internal stresses, including brittle lacquer materials, cantilever beams, optical, strain gauges, and X-ray diffraction. The cantilever beam method is most widely used and gives suitable measurements. This method depends on the fact that a coating under stress on a substrate will deflect in the direction that will relieve the stress. There are two types of cantilever beam used. A one-side coated substrate is either fixed at one end or is freely supported on two knife edges. The deflection in either case can be measured;
if the elastic properties of the substrate are known, the internal stress can be calculated.

4.9 Chemical Resistance

Coatings are the first-line defense for a product that contacts hostile environments. They protect many products from a variety of chemicals. In addition to protecting the product, it is preferable that the coating does not stain, does not lose adhesion, does not lose gloss, and is not permanently altered in any way by its contact with the hostile conditions.

Household chemicals include alkaline and acid solutions, beverages, condiments, cosmetics, edible and inedible oils and greases, ethyl alcohol, fruit juices, hot and cold water, soap and detergent solutions, vinegar, as well as many other common compounds. These compounds can be placed on coatings and either left open to the air or covered by a watch-glass to determine the effect of the compounds on adhesion, blistering, gloss, softening, and other properties of the coating. Each compound is examined in a particular manner. For example, hot coffee is poured onto a coated panel held in a horizontal position and allowed to dry. The coating is then examined for spotting, softening, graying, staining, or any other deterioration. Cosmetics are applied to the coating and placed overnight in a 50°C oven. The coating is then examined for film failure and discoloration.

Various coatings used in the transportation industry are tested in a somewhat similar manner. However, in some instances, the test includes exposure to either sunlight or ultraviolet light for a specified time; increased temperature is an important additional variable if hot, sunny climates are being simulated. Some of the chemicals important to transportation coatings are alcoholic windshield-washing solutions, antifreeze compounds, gasoline, hydraulic fluids, lubricating greases and oils, polishes, and road oils and tars. An immer-

5 END-USES

Earlier discussions of coating uses indicated the wide variety of end-uses. Testing of coatings can be fundamental and sophisticated in nature or it can be quick and simple to accomplish. Testing may be done to meet a set of specifications set by the supplier and by the seller or user. Testing is determined with free films.

5.1 Tests Required for Specific End-uses

Although the specific tests described below are referenced, often a buyer and a seller will define certain requirements that must be met by tests such as these or those that will define mutually acceptable testing criteria.

Aerospace and aircraft coatings are tested for adhesion under ambient conditions and under specific environments, such as after water immersion with the Scotch tape peel test. Scrape adhesion is also important. Flexibility is determined by the mandrel bend test at temperatures as low as −51°C. Toughness is determined by measuring impact resistance with the falling weight test (see above) and/or with a G. W. Impact-flexibility Tester. The latter test involves dropping a steel cylinder that has spherical knobs on its surface onto a coated panel. The knobs will subject the coating to elongations of 0.5–60% under the conditions of the test. Other important mechanical properties include hardness and mar resistance. Tensile properties are determined with free films.
The aluminum and steel beverage container industry is a large consumer of coatings and requires coatings to have high-quality mechanical characteristics in addition to meeting governmental regulations for safety and health. The inside and the outside of the cans are coated but with different coatings. The inside coating provides protection of the metal can from its contents as well as protection of the contents from taste alteration or contamination by contact with the metal can. The outside coating provides attractive, product identification. Important mechanical properties include abrasion resistance, adhesion, hardness, and flexibility. Pipelines carry oil, natural gas, water, and chemicals to plants and to consumers. Often the product is transported for long distances and often these pipes are buried underground and, thus, have a constant pressure applied. During the burial process, dirt, stones, and rocks are thrown into the trench and the coatings must have sufficient toughness to withstand this rough handling. Chemical plants and refineries use extensive pipeline systems to carry raw materials to reactors, intermediates to separation or other reaction systems, and final products to shipping facilities. The coatings must have sufficient integrity to withstand the hostile environments associated with such use. Above- and below-ground pipes are subjected to expansions and contractions as the temperature changes; again toughness and flexibility are important factors. Although pipelines are efficient means to carry out such operations, they must be protected by coatings to ensure dependable service and long life.

Automotive coatings are subjected to mechanical abuse from ordinary usage and from nature. Although individual automobile manufacturers have specific testing protocols involving test methods devised in-house, they often use many of the tests described above. A variety of substrates are involved and range from those that are flexible to those that are rigid; the coatings range from primers, to guide coats, to topcoats, etc. Hardness is determined by the Tukon indentation method and wear resistance by the Taber Abraser method. Adhesion is determined by either X-scribing or cross-hatching and applying pressure-sensitive tape under ambient conditions and after exposure to 100% RH. Coatings must have at least 99% adhesion when tested by these methods. To test resistance to impact from stones and road debris, a gravemeter test is used. Toughness is ascertained by scraping coatings on rigid substrates with a dime and by scraping with a knife when the coating is on flexible substrates. When these scraping tests are used, the coating should not flake, peel, or lose adhesion. Resistance to water and to saline solutions are important aspects of transportation coatings.

Testing of coatings is usually carried out before the coating is chosen for an end-use in order to assess when or how the coating will fail, if it does, when in use. Many coatings are used to protect substrates and thus preserve materials and conserve natural resources; as such, coatings are environmentally sound in nature. Although they can be well designed, coatings can and do fail. Therefore, it is also important to investigate coatings when they have failed to determine the reasons for failure. Mills has given an excellent description of coating failure analysis.

Fundamental research on films and the development and optimization of coatings are not possible without high-resolution imaging. This article describes the advantages and disadvantages of the newly introduced scanning probe microscopy (SPM) in comparison with well-established microscopy techniques with light and particles [e.g. scanning electron microscopy (SEM) and transmission electron microscopy (TEM)], which are limited by the diffraction limit, i.e. 200 nm for conventional light microscopy and 4 nm for SEM. This limit does not hold for SPM, which uses near-field interactions for imaging. Thus, even simple atoms or molecules can be resolved on well-ordered structures by scanning tunneling microscopy (STM) or atomic force microscopy (AFM). Both possess an extremely good height sensitivity of 0.02 nm.\(^1\) In the constant-height operation mode, AFM can detect vertical forces as low as \(10^{-15} - 10^{-14} \text{ N}\). Atomic resolution is not always possible or not always necessary for many practical applications; a lateral resolution of a few nanometers is sufficient. Besides the capability of achieving this value with ease, simple sample preparation, versatile environmental conditions and observation of reactions in situ are advantages of STM and AFM.

Especially AFM has proved to be a useful technique for investigating coatings, because it is independent of conductivity and provides topographic data together with information on structure, local variations of mechanical properties and surface alterations in different media. However, some artifacts and restrictions have to be considered which can differ considerably from customary electron micrographs with comparable resolutions, such as onset overswing and tip convolution.

Microscopy helps in solving coating problems according to substrate quality, nucleation, wettability, thickness, roughness, microstructure, crystal phases (texture, orientation), lateral and vertical homogeneity, density, porosity, interfaces, adhesion, hardness, stress, scratch and abrasion resistance, tribology, wear and corrosion. Practical examples of microscopy results on these questions are presented together with suitable preparation methods and interpretation of artifacts.

---

1 THE ROLE OF IMAGING TECHNIQUES DURING DEVELOPMENT AND INVESTIGATION OF COATINGS

The performance of coatings is dependent on their morphology to a great extent. Microscopy is an indispensable tool for the development of coatings as it provides topographic information from nucleation to corrosion and wear during application. Thin coatings with a thickness below 1 µm are becoming more and more important and
many different coating and substrate materials are being combined, hence instruments with high resolution are demanded. Instruments are preferred which can cope, e.g. with both conducting and nonconducting materials and combine topographic information with information on other properties such as crystal structure or local variations in chemistry. Because of their versatility, simple handling and unpretentious sample preparation, the use of scanning probe microscopes has expanded rapidly and is still expanding.

2 METHODS

2.1 History of Modern Microscopy Techniques

Microscopy means magnified imaging of objects. Conventional microscopy techniques can be classified with respect to the type of interaction that they use and the resulting magnification:

1. electromagnetic radiation, waves:
   (a) optical microscopy
   (b) X-ray microscopy
   (c) scanning acoustic microscopy

2. particles:
   (a) SEM
   (b) TEM
   (c) field ion microscopy (FIM).

Two-dimensional mapping and magnification of objects are achieved by either geometrical optics or scanning in small steps. The methods mentioned above detect reflected or secondary electromagnetic or particle beams in the far field.

The newly developed scanning probe microscopes measure near-field interactions. Therefore, they are not restricted by the length of the probing wave.

The first ideas on exploiting near-field interactions for microscopy were published by Synge. In 1928 he proposed scanning an illuminated sample with a fine glass tip and measuring the near-field interaction of the evanescent electromagnetic field. With the help of an extremely fine aperture, the Abbe limit of diffraction can be avoided and the lateral resolution is no longer limited to half of the wavelength of the applied beam. Synge even proposed piezoelectric material for scanners. However, it was not before the 1980s that piezoelectric actuators with sufficient precision were available and his ideas were realized.

In 1986, Gerhard Binnig and Heinrich Rohrer received the Nobel Prize for Physics for the realization of the first SPM technique, STM, which 4 years before had visualized atoms for the first time. In 1985, Binnig et al. developed also the second type of SPM technique, AFM, together with Gerber and Quate.

2.2 Principles of Scanning Probe Microscopy

The common principle of all scanning probe microscopes is depicted in Figure 1. A fine tip is brought close to the sample surface. Within distances of few nanometers or even less than 1 nm, near-field interactions are measured (see Table 1). Scanning either the tip or the sample in the x and y directions with a step precision of 1 pm results in images of the height or other sample properties.

The measured types of interaction are as follows:

- the current of electrons tunneling between a conductive sample and a conductive tip in STM;
- Coulomb, Van der Waals and other forces between the sample and a fine tip on a spring cantilever in AFM;
- the evanescent electromagnetic field which is detected with a glass fiber above an illuminated sample in scanning near-field optical microscopy (SNOM).

Further types of SPM instruments are described in section 2.5. In this section, only a brief explanation of the method principles is given, as far as is necessary to comprehend preparation methods and possible artifacts during the measurement of coatings. Fundamentals and further information on SPM can be found in the article

![Figure 1](image)

### 2.3 Principles of Atomic Force Microscopy

#### 2.3.1 Components of an Atomic Force Microscope

Of all types of SPM, AFM is most widespread and frequently used for the investigation of coatings. In Figure 2 the five main parts of an AFM instrument are depicted:

- a fine tip at a soft cantilever spring;
- a detector for the spring deflection;
- a feedback loop which controls the movements of the microscope;
- actuators which move either the tip or the sample;
- an image processor which produces three-dimensional pictures of the $x$–$y$ position on the sample and the height or tip deflection as a $z$ value.

As a first step, the tip is brought close to the sample surface manually or automatically. Attractive forces can be detected at a distance of some tens of nanometers. In the most commonly used contact mode, the tip is made to approach the surface until attractive and repulsive forces are roughly balanced, i.e. within less than 1 nm. At a certain deflection of the cantilever, the actuator starts scanning the sample.

Common cantilevers are produced from Si or Si$_3$N$_4$ with integrated tips of the same material (see also section 2.3.2 on AFM tips). Typical spring constants for commercial cantilevers are 0.06–0.6 N m$^{-1}$. An easy way to detect the cantilever deflection is by reflection of a laser beam towards a partitioned photodiode (see Figure 2). This optical geometry is the only way to detect extremely low forces of about 10$^{-8}$ N. With a typical cantilever length of 100–200 µm, the optical system enhances deflections by a factor of about 1000 and allows the detection of deflections below 0.1 nm.

Other ways to detect spring deflections as low as 10$^{-9}$ nm are as follows:

- tunneling contact on a conductive cantilever;
- optical interferometry;
- measurement of capacity;
- piezoelectric cantilevers.

Force detection can also be achieved with a minute quartz resonator instead of the cantilever spring.

The signal of the photodiode is fed into the feedback circuit to keep the deflection constant by adjusting the height of the sample during scanning. The image processor then produces a three-dimensional image of the point $x$–$y$ on the sample and the $z$ voltage of the actuator.

A reliable type of actuator is a single-tube piezoelectric ceramic, but three orthogonally arranged piezoceramic bars and bimorphs have also been used. A common piezoceramic material is doped lead zirconium titanate with a typical elongation of 5 nm V$^{-1}$. Single-tube scanners with partitioned electrodes on their surfaces bend in the $x$ and $y$ directions and shrink and elongate in the $z$ direction as shown in Figure 3.

The maximum scan range depends on the length of the scanner. Typically, $x$–$y$ ranges of 1 µm$^2$ are achieved with a length of 1 cm. Large scanners with a length of some centimeters can scan over 100 µm$^2$. In Figure 2, the scanner moves the sample and the tip is fixed. In STM or AFM instruments with large sample stages or other than contact mode imaging, the sample is fixed and the tip is moved.

To protect the system from spurious vibrations, a rigid construction of the measuring head and good isolation from external vibrations are demanded. Means of vibration isolation such as silicone-rubber pads, bungee cords, eddy current damping and damping stacks with Viton fluoroelastomer are employed for protection from structural-borne noise in the 1-Hz frequency range. The first STM system was isolated from disturbances such as door slamming by sophisticated eddy current damping.
with superconductive liquid He,\textsuperscript{(43)} which proved to be oversized. In addition to structural-borne noise, constant sources of acoustic noise should also be avoided.

### 2.3.2 Tips in Atomic Force Microscopy

Commercial tips are produced via photolithography and chemical vapor deposition (CVD) processes.\textsuperscript{(44)} For easy handling, the cantilever and tip are integrated into a glass or Si chip. Typical materials for cantilevers and tips are Si and Si$_3$N$_4$,\textsuperscript{(45,46)} but diamond\textsuperscript{(7,26)} diamond-like carbon (DLC),\textsuperscript{(47)} thermal oxide grown on Si,\textsuperscript{(25,48,49)} GaAs,\textsuperscript{(50)} metals\textsuperscript{(51–55)} and glasses\textsuperscript{(56–58)} have also been used.

The most important parameters are the spring constant $k$ of the cantilever and the radius $R$ of the tip apex. For a rectangular cantilever, $k$ can be calculated from Young’s modulus $E$, length $l$, width $b$, thickness $d$ and density $\rho$ of the spring according to Equation (1)\textsuperscript{(22,27,44,59)}:

\[
k = \frac{Ed^3b(4l^3)^{-1}}{32} \tag{1}
\]

However, $d$ varies from tip to tip and cannot be measured precisely. Therefore, $k$ is better calculated from the measured resonance frequency $v_0$ as given in Equation (2)\textsuperscript{(59)}:

\[
k = \frac{2\pi^3\rho b^3}{\rho_E v_0^{1/2}} \tag{2}
\]

For Si, density and Young’s modulus are $\rho_{Si} = 2.33$ g cm$^{-3}$, and $E_{Si} = 1.79 \times 10^{11}$ N m$^{-2}$.\textsuperscript{(60)} Many cantilevers are V-shaped, and their spring constant $k_v$ is approximated by Equation (3)\textsuperscript{(61)}:

\[
k_v = 2k \tag{3}
\]

However, $\rho$ and $E$ also vary within wide ranges (by 50% and 600%, respectively), as the properties of thin CVD films may differ considerably from bulk material.\textsuperscript{(59,62)} For optical deflection detection, gold coatings are applied to enhance the reflectivity. They also change the mechanical properties. Therefore, each sensor has to be calibrated individually for precise force measurements. A precise but time-consuming approach is to measure the resonance frequency with and without an attached additional mass;\textsuperscript{(59,63)} $k$ can then be deduced from the two resonance frequencies and the known additional mass.

Magonov and Whangbo propose to vibrate the tip by enhancing the gains, which is a fast way to determine $v_0$.\textsuperscript{(22)} Sensors can also be bought with individual calibration.

For many practical applications, it is sufficient to know the relative force differences in arbitrary units instead of absolute values. Then, one can rely on average $k$ values. A sketch of the most commonly used Si$_3$N$_4$ and Si tips is given in Figure 4.

![Figure 4 Sketch of the most commonly used Si$_3$N$_4$ and Si cantilevers and tips.](image)

### 2.4 Operating Modes of the Atomic Force Microscope

#### 2.4.1 Contact Atomic Force Microscopy Height and Force Mode

The simplest mode of operation of AFM, the contact mode, has been briefly explained before. Height mode images are produced from the $x$, $y$ and $z$ voltage of the scanner with constant spring deflection. For force mode images, the $z$ voltage is kept constant and the deflection detector signal is transformed into force values. Although the physical interpretation of the force variations might be unclear (because of unknown $k$ or unknown absolute force), these images can be valuable for the interpretation of height mode images. Owing to a different way of amplification, they are more prone to overswinging and thus grain boundaries, coating interfaces, etc, can be readily recognized.

A typical AFM image consist of 256$^2$, 400$^2$, 512$^2$ or 1000$^2$ pixels. Generally, $x$ is called the fast scanning direction and $y$ the slow scanning direction. The time to sample an image depends on the scan size. For 400$^2$ pixel images larger than 1 $\mu$m$^2$, a frequency of 1–8 Hz (lines per second) is useful; for images smaller than 1 $\mu$m$^2$, 8–60 Hz might be sufficient. Scans of 1 $\mu$m$^2$ can be finished after less than 1 min. This is fast enough for in situ observations of changes due to chemical reactions or physical processes which can cause changes of the coating topography.

#### 2.4.2 Local Spectroscopy

In the STM spectroscopy mode, the tip is fixed at one point $x$–$y$ and the bias voltage is varied. A current versus voltage characteristic is registered, which gives information on local electronic properties. Corresponding to this local current spectroscopy, local force spectroscopy...
Figure 5 Idealized force–distance curves. (a) Force $F$ at the cantilever versus piezo elongation $z_P$. (b) Force–distance curve (hysteresis) if the scanner elongation is not sufficient for retracting the tip from the surface. (c) Force–distance curve with optimized scanning force. (d) Tip deflection $s_F$ and scanner elongation $z_P$.

(LFS) with an AFM instrument is achieved by keeping the tip at one point $x-y$ and varying the $z$ height. Force–distance curves give information on local forces between the tip and sample and local mechanical properties of coatings. LFS is recommended for adjusting a proper tip–sample distance for delicate samples. If the Young’s modulus of the tip is much larger than the sample modulus, local variation in sample elasticity can be imaged. By recording force–distance curves in electrolytes, the isoelectric point of the tip and/or the sample can be determined.

Figure 5(a) displays an idealized force–distance curve, i.e. cantilever deflection versus $z$-elongation of the piezo. For long distances between the tip and sample, there is no deflection (A). Approaching the range of attractive forces, the cantilever bends downwards to balance the attraction. As soon as the gradient of the attractive forces is higher than the spring constant, the tip abruptly deflects downwards and jumps to contact (B–C). If the distance is reduced still further, repulsive forces occur. Between D and E, the modulus of the tip and sample surface govern the force–distance curve. Because of adhesive forces and elastic, viscoelastic or plastic deformation and in the presence of liquid films, the tip has to be retracted further than the former point of jump to contact before it is set free (F–G). The gradient $k = \Delta F/\Delta z$ of the repulsive part of the LFS curve (C–E) depends upon the spring constant of the cantilever and the Young’s modulus of the sample. This part serves for investigations of the elastic properties. Hardness is calculated from the retraction behavior by subtracting the elastic component. Hardness is defined by the maximum load divided by the contact area after elastic recovery of the sample. The force which is necessary to break the contact depends on the sample and can serve for material characterization.

The great advantage over conventional indenters is that AFM can provide information also on thin coatings, as the indentation depth and load can be much smaller. Besides the thin liquid water film present in laboratory conditions, thin liquid films may also be present on the sample surface, which can affect the results of the measurements. Therefore, it is important to consider the presence of such films when interpreting the obtained data.
air, other contaminant layers and lubricants can disturb the measurement and lead to additional kinks in the force–distance curve.\(^{(5)}\)

Figure 5(b) shows the force–distance curve for too small \(z\) variations. In this case, the tip cannot spring free. Figure 5(c) gives an example of how to minimize interaction forces on delicate samples. With a contact area of 100–400 nm\(^2\) and a load of some nanonewtons, the mechanical pressure under the tip is 10\(^7\) Pa.\(^{(50,63)}\) Loubet et al. gave an estimation of 3 nm for the contact radius \(r_C\) and 2 \(\times\) 10\(^9\) Pa for the pressure.\(^{(73)}\) To minimize sample or tip destruction, measurements should be made at zero force. Therefore, the tip is retracted to a point where it still keeps in contact\(^{(22,69,74)}\) and the piezo elongation for scanning is set to the setpoint depicted in Figure 5(c).

The tip–sample distance \(d\) depends on the distance \(d_0\) before the spectroscopy measurements, the elongation \(z_p\) of the piezo and the cantilever deflection \(s_F\) (see Figure 5d) (Equation 4):

\[
d \approx d_0 + z_p + s_F
\]

Taking into account only cantilever deflection (no other deformations), one can write:

- \(s_F = 0\) from A to B and at D
- \(s_F < 0\) from B to D
- \(d = r_C\) from C to E (\(r_C =\) contact radius)
- \(s_F > 0\) from D to E

With unknown sample deformation, an exact value of \(d\) cannot be given.

Depending on the strength of the interaction and on the sample reaction, there are different types of LFS curves.\(^{(1)}\) With strong tip–sample interaction, the tip jumps into contact and out of contact (B–C and F–G are steep). With relatively high spring constant \(k\), the tip slides in and out (B–C and F–G are flat). On some surfaces, a mix of these two types is observed: jump in/slide out (B–C and F–G are steep). On some surfaces, a mix of these two types is observed: jump in/slide out (B–C and F–G are steep).

With known tip radius \(R\), the Hamaker constant \(A\) can be calculated from the interaction energy \(E_{SP}\) and the force \(F_{SP}\) in the attractive part of the LFS curve (Equations 5 and 6):

\[
E_{SP} = -AR(6d)^{-1}
\]

\[
F_{SP} = -\partial E_{SP}(\partial d)^{-1} = -AR(6d^2)^{-1} = -kz
\]

\(A\) depends on the density of the tip and sample material, their dipole interaction and the surrounding medium. From the LFS of graphite in air, Burnham and Colton calculated \(A = 3.2 \times 10^{-19}\) J.\(^{(1)}\) However, the true effective interaction radius can be different from the microscopic tip radius. The interaction is dominated by the smaller radius of curvature of rough asperities on the tip.\(^{(60)}\)

Capillary forces affect the force measurements in a humid environment. A meniscus is formed between the tip and liquid layers if the radius of curvature of the tip–sample contact is smaller than the Kelvin radius \(r_{Kelvin}\) (see Figure 6); \(r_{Kelvin}\) is determined from the radius of the capillary, \(r_1\), and the radius of curvature, \(r_2\), of its surface (Equation 7):\(^{(75)}\)

\[
r_{Kelvin} = r_1r_2(1 + r_2)^{-1}
\]

where \(r_1\) and \(r_2\) depend on the relative vapor pressure.\(^{(75)}\) With a relative humidity of 90% at 20°C, \(r_{Kelvin}\) for water is of the order of 10 nm, and at 30–40% it becomes \(r_{Kelvin} \approx 1\) nm. For low vapor pressures (about 10% relative humidity), Equation (7) would render \(r_{Kelvin}\) in the range of molecular radii and it can no longer be used.\(^{(28,75)}\) Below 10% relative humidity, the water capillary evaporates.

### 2.4.3 Lateral Force Microscopy

Deflection detectors for the lateral force microscopy (LFM) mode are split into four sectors and can separate normal and lateral forces.\(^{(76)}\) Lateral force differences, i.e., torsion of the cantilever, are due to variations in friction resulting from different gradients, different roughness or different materials on the sample surface. By changing the fast scanning direction from parallel (ideally no lateral forces) to perpendicular (ideally maximum lateral forces) to the cantilever beam and by comparing scans in the \(x\) and \(-x\) directions, roughness and height differences can be distinguished.\(^{(22)}\) On flat surfaces, material contrasts can be visualized, which is extremely helpful for the investigation of multiphase coatings and the first stages of layer growth.

LFM opens up a new research field for tribology in the nanometer world.\(^{(73,77–81)}\) First theoretical explanations for the nanotribological behavior of the tip–sample system are under development.\(^{(82,83)}\)
2.4.4 Non-contact Mode (Attractive Mode)

In the non-contact mode, which was introduced by Martin et al.,\(^\text{(29)}\) a relatively stiff cantilever with \(k \approx 100 \text{ N m}^{-1}\) is scanned within a distance from 1 nm to some tens of nanometers above the sample.\(^\text{(91)}\) The tip is vibrated and the frequency shift or the variation of the free amplitude is detected. At this distance, attractive Van der Waals and capillary forces dominate\(^\text{(34,85)}\) which are about 10\(^5\) times weaker than the repulsive forces in the contact mode. At smaller distances, covalent forces between the dangling bonds of adatoms on the sample and the top also contribute to the contrast.\(^\text{(86)}\)

Noncontact mode scanning is recommended for soft surfaces which are not stable when scanned in the contact mode. Van der Waals forces can be measured with a sensitivity of 10\(^{-13}\) N and force gradients with 10\(^{-6}\) N m\(^{-1}\).\(^\text{(87)}\) However, 10–30 monolayers of H\(_2\)O + N\(_2\) on samples in humid air can hinder stable noncontact mode measurements, as the thickness of these layers might be in the same range as the scanning distance.

2.4.5 Tapping™ or Intermittent Contact Mode

With tip vibration amplitudes of 10–100 nm, the liquid layer on samples under ambient conditions no longer causes unstable oscillations and the tip springs free from the layer with each oscillation.\(^\text{(88)}\) Vertical forces might be high in this intermittent contact mode. Its was found, however, that vertical forces are not as detrimental for delicate surfaces as the lateral forces which occur during contact mode scanning.\(^\text{(22,89)}\) Digital Instruments chose the name Tapping™ for this mode, as the tip taps each image pixel from above, instead of scratching along a line. With tapping frequencies of about 200–400 Hz, each pixel is touched a few times.\(^\text{(90)}\) Height images are gained from the variation in the free amplitude.

Phase contrast can also be recorded in this mode; it can contain information on topography and on local chemical variations.\(^\text{(90–92)}\)

2.4.6 Force Modulation

For force modulation measurements, the tip is also vibrated, but with a smaller amplitude than for noncontact or intermittent contact mode. The tip stays in contact with the surface and images material contrasts by recording local variations in elasticity.\(^\text{(93,94)}\)

Modes with modulations of the tip–sample distance such as noncontact, intermittent contact or force modulation are called AC methods or dynamic modes. Quasi-static methods without distance modulation are called DC methods.

2.4.7 Environmental Conditions: From Ultrahigh Vacuum to Liquid Media

SPM is very versatile regarding the environment for measurement: scanning is possible in ultrahigh vacuum (UHV), in air or in liquids,\(^\text{(6,95,96)}\) and temperatures between 400 and 4 K are possible.\(^\text{(34,35,41,42,97–100)}\) The atmosphere can be controlled by performing SPM in a glove-box\(^\text{(101)}\) or by sweeping the sample with well-defined gases.\(^\text{(102)}\)

In liquids, capillary forces are avoided and Van der Waals forces are one to two orders of magnitude smaller than in humid air,\(^\text{(74)}\) and electric double layers can be observed. Scanning in a liquid cell opens up new fields for AFM in biology and electrochemistry and for the investigation of crystal growth and corrosion of coating materials. Depending on the scanning frequencies, dissolution or growth rates from 10\(^{-10}\) to 10\(^{-16}\) mol m\(^{-2}\) s\(^{-1}\) are observable.\(^\text{(103)}\) Another way of avoiding the liquid water film is the investigation of frozen samples.\(^\text{(104)}\)

2.5 Various Types of Scanning Probe Microscopy

Instrument

Based on the first STM technique, more than 20 various types of near-field microscopes have been developed\(^\text{(105)}\) and overviews have been published.\(^\text{(85,87,106–111)}\) The main difference between these types of SPM instruments is the type of sensor, which renders locally resolved near-field information. Some common SPM instruments, which are useful for coating investigations, are presented in Table 2. They are briefly discussed below, ordered according to the type of interaction measured.

2.5.1 Current, Electric Interaction

An STM instrument measures the current of tunneling electrons between a conductive tip and a conductive surface. Typically, the sensor is a fine metal wire. On the tip apex, minitips with an effective radius of curvature < 5 nm can provide atomic resolution on many ordered surfaces. With typical distances of 0.3–1 nm, a bias of 1 mV to some volts between the tip and surface renders a detectable current of 20 pA–10 nA. The distance tolerance is 0.001 nm.\(^\text{(116)}\)

The distance tolerance in scanning noise microscopy (SNM) is smaller. This microscope works like an STM instrument without external bias. Therefore, it is not as well suited for rough coatings. Distance control by tunneling noise can be helpful for other applications. The low signal is acceptable if for electrochemistry investigations or for sensitive samples a small or disappearing current is desired.\(^\text{(106)}\) Scanning ion conductance microscopy

(SICM) measures ion currents. The sensor consists of a glass micropipet with a tip radius of about 100 nm. The micropipet and the sample are contained in an electrolyte solution.\(^{85,126}\)

The scanning capacity microscope measures the capacity of the tunneling barrier with a metal wire as a sensor; this capacity is of the order of attofarad (10\(^{-16}\) F).\(^{34}\) The combination of metal wire, tunneling gap and Si acts like a MIS-diode (metal–insulator–semiconductor) and can be used for recording dopant profiles. Variation of the external bias serves for scanning capacitance spectrometry and is helpful for the investigation of, for example, charge storage devices.\(^{33,107}\)

### 2.5.2 Forces and Mechanical Sample Properties

AFM and LFM, which measure vertical and lateral forces with a tip and cantilever, were described in section 2.4.

Force modulation measurements of organic coatings on mica in air led to the surprising result that mica appeared softer than monolayers of a self-organizing hydrosilicon.\(^92\) A combined instrument with an optical microscope, an LFM instrument and a Vickers nanohardness tester was developed by the Centre Suisse d’Electronique et de Microtechnique (CSEM) in Neuchâtel, Switzerland.\(^{114}\) The sample is transferred between the three stations with extremely high precision to hit the same area in all three tests. Scholl et al. use the AFM instrument itself as an indenter; they indented the sample with a special W-tip and imaged the indentation with a commercial AFM tip.\(^{115}\) Bhushan et al. used three-sided diamonds as tips and cantilevers of steel as nanoindents with normal loads of 10–150 \(\mu\)N, as scratch testers at 1–100 \(\mu\)N and for AFM imaging at 0.3 \(\mu\)N.\(^{127}\)

For the measurement of magnetic forces only a small modification of the AFM system is necessary. AFM cantilevers with a magnetic coating or L-shaped wire of Fe, Ni or W can render information on magnetic domains and are especially interesting for the investigation of thin magnetic films.\(^{54,107,128}\) Because of the relatively long range of magnetic dipole forces, the resolution of magnetic force microscopy (MFM) is restricted to 10–50 nm.\(^{22}\) Jarvis and Pethica detected environmental water films with the help of hydrophobized MFM.\(^{129}\)

### 2.5.3 Microwaves and Light

Coaxial metal hollow wave conductors with an aperture of 2 mm and a central wire with a radius of 6 \(\mu\)m can measure the tunneling current and microwave conductance of thin films or semiconductors instantaneously.\(^{130}\) High-frequency scanning electrical force microscopy (HFSEM) is a noncontact AFM technique with a coplanar waveguide integrated into the cantilever for the investigation of microwave components in the 10-GHz range.\(^{50}\)

In SNOM, nonradiative electromagnetic near-field interaction serves for imaging.\(^{116,117}\) These interactions have a decay length shorter than the wavelength. Therefore, the diffraction limit of optical microscopy (see Equation 8, section 2.6) does not hold. Any inhomogeneity in a radiation field becomes a source of radiation, an antenna, whose dielectric and magnetic near-field properties can be characterized with the help of its far field.\(^{116}\) The antenna can be used as a transmitter and receiver or only as a receiver. Investigations can be conducted in transmission or in reflection. This gives rise to a variety of different construction principles of SNOM with different acronyms. SNOM is used here for all these different types of optical near-field microscopy techniques.

Micropipets or glass fibers with tip radii <100 nm serve as sensors. Another way of producing a small aperture is a metallic coating with a tiny hole on a glass fiber or a glass slide.\(^{116,117,121}\)

In contrast to AFM, SNOM is not sensitive to electrical charges.\(^{131}\) As in all near-field interactions, the optical near-field signals are strongly dependent on the distance. Typical measurement distances for SNOM in the infrared region are 0.2–5 \(\mu\)m,\(^{16,119}\) for SNOM with visual wavelengths below 10 nm.\(^{132}\) There are different concepts for distance control: glass fibers with conductive coatings can use photon tunneling; in other SNOM techniques control is effected by shearing forces on the tip\(^{133}\) or by capacity.\(^{119,134}\)

The resolution is limited by the aperture and measuring distance. By reducing the measuring distance to 2–5 nm the resolution could be improved from about 700 to 25 nm.\(^{135}\)

Inverse photoemission spectrometry (STM-LE) derives advantage from the inverse photo effect by detecting the light emission caused by tunneling electrons.\(^{15,87,116,123}\) STM-LE is comparable to cathodoluminescence imaging in SEM. The quantum yield is much lower, about 10\(^{-4}\) photons per tunneling electron, and most of the tunneling electrons only heat the sample.\(^{106}\) In spite of this fact, the aim is to develop a chemical surface analysis via STM-LE.

### 2.5.4 Temperature, Heat and Acoustic Waves

The probe in scanning thermal microscopy (SThM) is a fine thermoelectric couple made of a W wire coated with an isolator and Ni. Tip radii of about 15 nm have been achieved.\(^{85}\) For scanning thermal microscopes with Pt/PtRh thermoelectric couples a lateral resolution of from micrometers\(^{124}\) to 35 nm has been reported.\(^{85}\) In addition to local temperature measurements with a precision of 10\(^{-4}\) K, SThM can serve for chemical
analysis if it is combined with a photothermal absorption spectrometer. The sample is irradiated with a tunable laser. Absorption and thus heating of the sample are wavelength dependent and specific for elements.\textsuperscript{(85)}

A calorimeter with nanometer precision must itself have a small heat capacity. This demand is fulfilled by Si AFM tips with an Al coating which bend like a bimetallic strip owing to temperature changes. They can indicate 1 nJ.\textsuperscript{(125)}

In tunneling acoustic microscopy (TAM) the probing tip is excited with ultrasonic vibrations close to the resonance frequency of sample, sample holder and piezoelectric transducer. Depending on the distance, another transducer indicates the transmittance to the sample.\textsuperscript{(106)} Theoretically, a local resolution of 20 nm should be possible; in practice commercial systems reach 0.5 µm.\textsuperscript{(136)} An instrument with two springs, one as a transmitter and the other as a receiver, detects pores, flaws or other inhomogeneities in the sample volumes.\textsuperscript{(108)}

### 2.6 Comparison of Microscopy Methods

Because of the diffraction limit, the spatial resolution of conventional microscopes is dependent essentially on the wavelength of the type of radiation used (see Table 3). According to a relation which was initially established by Ernst Abbe for light microscopy, the spatial resolution limit \( d_c \) of conventional microscopes is dependent on the aperture \( a \), the refractive index \( n \) of the medium and a constant \( k \) describing the brightness of the object:\textsuperscript{(137–140)}

(Equation 8):

\[
d_c = k \lambda (n \sin a)^{-1}
\]

The essential factor is the wavelength \( \lambda \) of the type of radiation used. Equation (8) can be roughly estimated by \( d_c = 0.5 \lambda \).\textsuperscript{(137,138)} Lens aberrations can prevent this theoretical limit from being reached.

Optical polarization microscopes can image height distances of around 0.1 nm and measure roughness\textsuperscript{(143)} (see section 2.7), with a rather poor lateral resolution of 1 µm. An optical microscope with an outstanding capability of imaging the topography of coatings is the Nomarsky or differential interference contrast microscope.\textsuperscript{(144,145)} Its depth of focus is smaller than that of electron microscopes, which makes it more sensitive to surface features. Nomarsky images can also be transferred to digital data.

The lateral resolution of confocal laser scanning microscopy is better than that of conventional light microscopy by a factor of 1.4. Further advantages of this method are the reduction of stray light from neighboring structures and instantaneous three-dimensional data sets.\textsuperscript{(146)}

In an electron microscope, a beam of accelerated electrons is used instead of electromagnetic radiation, and electromagnetic lenses take the role of the glass lenses in an optical microscope. The sample is either scanned (SEM) or directly imaged (TEM) by electrons on a fluorescent screen.

In SEM, the image can be reconstructed from secondary electrons, backscattered electrons, cathodoluminescence and some other interactions between the incident beam and sample.\textsuperscript{(139)} Its resolution is mainly limited by the diameter of the incident electron beam; optimum focusing results in \( d_c = 3–6 \text{ nm} \)\textsuperscript{(139)} and \( d_c \geq 10 \text{ nm} \) is typically achieved.\textsuperscript{(147)}

For direct imaging as in TEM, Equation (8) holds; in this case \( \lambda \) is the de Broglie wavelength \( \lambda_c \) of the electrons (Equation 9):

\[
\lambda_c = h (m_e v)^{-1}
\]

where \( h = 6.626 \times 10^{-34} \text{ J s} \) is Planck’s constant, \( m_e \) electron mass and \( v \) = electron velocity;\textsuperscript{(139)} \( v \) and thus \( \lambda \) depend on the acceleration bias, which is in the range of some tens of kilovolts to megavolts; relativistic effects are to be considered above 50 kV. Acceleration with 50 kV results in \( \lambda_c = 0.0053 \text{ nm} \).\textsuperscript{(148)}

Spherical and chromatic aberration lead to a worse practical resolution. In TEM, the chromatic aberration also depends on the sample thickness \( t \), \( d_c \approx 0.1 t \).\textsuperscript{(137,138)} An aperiodic resolution limit of about \( d_c = 0.2 \text{ nm} \) can be achieved in TEM with a 10 nm thick sample.\textsuperscript{(147)} TEM resolution can be sufficient for imaging large atomic distances in some ordered materials. With an acceleration voltage of 200 kV, even a lattice-fringe image resolution of 0.1 nm has been reached.\textsuperscript{(148)}

One large advantage of electron microscopes is that material properties contribute to the contrast as electron scattering and transmission depend on the element mass. Additionally, many electron microscopes are combined with elemental microanalysis via energy-dispersive X-ray spectrometry (EDX), wavelength-dispersive X-ray spectrometry (WDX) or crystal structure analysis via diffraction.\textsuperscript{(137,138)}

COATINGS
Some modern instruments no longer require high vacuum in the sample chamber. With a diaphragm between the microscope column and the specimen, wet materials and materials with volatile components can be imaged. The gas pressure between 10 and 1000 Pa in the sample chamber of such an environmental scanning electron microscopy (ESEM) instrument can also provide charge compensation during imaging of nonconducting samples.

In conventional electron microscopy, however, a conductive coating, generally C or Au, must be applied. This decoration masks sample features smaller than the grain size. A further restriction is given by the electron radiation damage in the irradiated zone of the sample. Therefore, TEM investigations on, for example, the crystal phases in nonconducting samples must be conducted fast and with low bias.

Scanning X-ray microscopes employ soft X-rays with a wavelength between 2 and 5 nm and achieve a spatial resolution of about 30 nm. Ion microprobe mass analysis (IMMA) images element distributions with a lateral resolution of micrometers.

Field ion microscopes achieve a magnification of the order of 10⁶ and can image individual atoms. However, they are restricted to atoms on fine tips with typical apex radii of 10 nm and cannot display flat coated samples.

In addition to the spatial resolution and information depth, other criteria for the choice of a certain type of microscope are the following:

- the contrast resolution (i.e. height resolution of topography images);
- the restrictions on sample size and sample properties;
- the expense of sample preparation (cleaning, decoration);
- the environment needed (high or medium vacuum, air, liquids);
- the time to sample one image;
- the availability and price of the instrument.

In any case, a comparison of images from different microscope types, starting with a low magnification and resolution, is recommended for unknown surfaces. Combined instruments utilizing AFM in an optical microscope or SEM and SPM in the same vacuum chamber are commercially available and eliminate the problems of sample transfer.

### 2.7 Determination of Roughness

A quantitative determination of roughness is part of a complete surface characterization of substrates and coatings. Roughness is an important parameter for topics such as surface energy, adhesion, optical quality, tribology and wear. According to Bennett, surface formations can be classified as follows depending on their lateral dimensions:

- microroughness or roughness with wavelengths up to about 1 mm;
- waviness or mid-frequency roughness with wavelengths from millimeters to centimeters;
- surface shape or optical shape with wavelengths from centimeters up to the dimensions of the object, especially deviations from the ideal shape.

A practical example of waviness is the “orange peel” of chemically polished Si wafers. Microroughness is the parameter which describes the quality of substrates and coatings. Deviating from these definitions, microscopists often use the term waviness for formations with lateral dimensions of the order of the image size, i.e. from <1 μm to some hundreds of micrometers.

Roughness is given, for example, as average roughness \( R_a \) (arithmetic average of all \( z \) values) (Equation 10):

\[
R_a = \frac{1}{N^2} \sum_{i=1}^{N} z_i = 0
\]

where \( N \) = number of pixels per line and lines per image and \( z_i = \) measured height at point \( i \), or as root mean square (RMS) roughness (geometric average of all \( z \) values, also called \( R_q \) or \( \sigma \)) (Equation 11):

\[
\text{RMS} = \frac{1}{N^2} \sum_{i=1}^{N} z_i^2
\]

The RMS roughness can be calculated from total integrated scattering (TIS) data according to Equation (12):

\[
\text{RMS} = \frac{\lambda}{4\pi} \frac{S}{R_0}
\]

where \( \lambda \) = wavelength of light, \( S \) = ratio of total stray light intensity to incident intensity and \( R_0 = \) reflection. For ideally isotropic surfaces with a Gaussian distribution of heights, the RMS values of line scans and area scans are identical.

Methods for determining roughness are described in DIN 4760 (RMS), ISO 4278/1 and ANSI/ASME B46.1 and in a report of the ASTM STM/AFM Subcommission E-42-141 (“standard practices for analyzing and reporting surface roughness as measured by STM/AFM”, http://www.atm.org). The ASTM Subcommission F-1.19 is working on a draft standard for calculating power spectral density (PSD) from surface profiles.

There are mainly two types of methods for the measurement of roughness: diffraction of electromagnetic
radiation or particle beams and optical or mechanical profilers. An overview of the methods and some recommendations according suitable methods for different surfaces were given by Bennett and Mattson\(^\text{144,154}\) and Rothe et al.\(^\text{156}\) Guenther et al.\(^\text{158}\) and Bhushan et al.\(^\text{155,159,160}\) compared optical and mechanical profilometry with different types of scanning force microscopes.

Roughness values can only be compared if the bandwidth range and the height sensitivity of the instrument used are known.\(^\text{144,155,161}\) The lower bandwidth limit is defined by the best achievable resolution or the number of measurement points per scan and the upper limit by the measured length or area on the sample surface.

Optical methods such as scattering of light [TIS, angle resolved scattering (ARS)], small-angle diffraction of X-rays (SAXS), or small-angle scattering of neutrons (SANS) and grazing incidence X-ray reflection (GIXR) give average roughness values for spots in the order of square millimeters.

The upper bandwidth limit in SPM can range from about 100\(\mu m\) down to nanometers. For analysis with GIXR or optical interferometry, an assumption regarding the height distribution is required. In many cases, a Gaussian distribution works well.\(^\text{162}\) In contrast, the real height distribution is measured with mechanical profilers or by SPM.

Anisotropies of diffraction data give indirect hints on the type of the defects (e.g. scratches, holes, dust) that contribute to the roughness of optical surfaces. True defect profiles cannot be deduced from the distribution of diffraction intensities.\(^\text{163}\) Two-dimensional profilers and scanning probe microscopes simultaneously provide data on roughness and direct images of the profiles in real space.

An evaluation of the information from different roughness measurement methods was given by Rothe et al.\(^\text{156}\) and the capabilities of AFM and X-ray scattering have been compared.\(^\text{164}\) As is shown in Figure 7, SPM has the largest bandwidth. Owing to its capability to resolve even single atoms (at least on some favorable flat surfaces), it can determine differences between extremely smooth samples. It can detect wavelengths from the resolution limit (atomic distances to at least some ten of nanometers) up to the maximum \(x\)–\(y\) range of the scanners (about 100\(\mu m\)) and height differences from 0.01 nm to some micrometers.

The bandwidth of the measurement must be chosen with respect to the practical application and the physical parameters implicated. The important length scale can be the area of contact between the recording head and magnetic storage media, the wavelength of visible light for optical coatings or atomic distances for tribology of extremely smooth surfaces.\(^\text{155}\) Frequently, the measured roughness values increase with increasing upper bandwidth limit up to a certain saturation value. In such cases, the upper bandwidth limit may be set to the point, where no longer wavelengths are observed.\(^\text{155}\)

For the comparison of bandwidth ranges, a surface profile \(z(x)\) can be described by sine waves as in Equation (13):

\[
z(x) = Z \sin \left( \frac{2\pi x}{\lambda} \right)
\]  

where \(Z = \text{amplitude}\) and \(\lambda = \text{wavelength}\). The working range of an instrument for roughness analysis is defined by straight lines in a log \(Z = f(\log \lambda)\) plot (see Figure 8):\(^\text{165}\)

- minimum and maximum detectable wavelength;
- minimum and maximum detectable height;
- maximum detectable gradient; for scanning probe microscopes, the detectable gradient is dependent on the tip angle 2\(\alpha\), limited by the straight line according to Equation (14):

\[
\log Z = \log \left( \frac{90^\circ - \alpha}{2\pi} - \frac{\alpha}{2\pi} \right) + \log \lambda
\]  

- minimum detectable radius of curvature \(R_{\text{min}} = R + r_w\), depending on the tip radius \(R\) and the interaction distance \(r_w\), limited by the straight lines according to Equation (15):

\[
\log Z = -\log(4\pi^2R_{\text{min}}) + 2\log \lambda
\]

The lower limit for the detectable wavelengths is defined by the resolution limit or the distance between to measurement points. AFM has a lower wavelength limit in the nanometer range; for mechanical profilers, this limit is between 0.1 and 1\(\mu m\). The upper wavelength limit, which is defined by the scan size, is about 100\(\mu m\) for SPM and some micrometers for profilers.

Because of different bandwidth limitations, roughness values measured on the same samples with different measurement methods was given by Rothe et al.\(^\text{156}\) Guenther et al.\(^\text{158}\) and Bhushan et al.\(^\text{155,159,160}\) compared optical and mechanical profilometry with different types of scanning force microscopes.
instruments can deviate. Apparent contradictions can be explained by a two-dimensional Fourier analysis of the profiles. By plotting the PSD against frequency, the fractal dimension can be calculated. With PSD curves from measurements with different bandwidths, the surface roughness can be analyzed over seven decades of wavenumbers.\(^{162}\)

### 3 SAMPLE PREPARATION

Similarly to all other high-resolution surface analyses, the sample preparation for SPM must be carried out with care to avoid unwanted alterations of the surface of interest. SPM samples must be sufficiently stable mechanically and chemically. Mechanically unstable specimens, e.g., aerogels, are vibrated by the tip in contact mode AFM. There are also less interactive measuring modes such as noncontact AFM which can image such delicate materials\(^{166}\) and soft coatings, e.g., not fully consolidated gels.

#### 3.1 Cleaning

The best way to avoid unwanted alterations of unknown surfaces is to apply no cleaning at all. If there is too much visible dust or a test scan results in unacceptable disturbances, blowing the dirt off with a bellows can be sufficient in many cases. Pressurized air can contain unctuous contaminants from the compressor. Large solid dust particles can interfere with the cantilever beam and soft dirt affects the image quality by sticking to the tip or smearing across the sample.

Many chemical, mechanical and physical standard procedures for the cleaning of optical surfaces or of substrates prior to coating can also be used for SPM samples. An overview of such methods was given by Dunken.\(^{167}\) Most oxidic coatings withstand a procedure with the following steps:

1. brushing with a nylon brush in hot water with a mild surfactant;
2. rinsing with deionized water;
3. ultrasonic bath in
   (a) acetone
   (b) ethanol
   (c) methanol;
4. drying in air, with a bellows or in dry nitrogen.

Steps 3 and 4 are repeated until the surface dries without visible stains. Some contaminants require wiping with soft tissue between the ultrasonic treatments. One way of removing hydrocarbons without mechanical contact is ultraviolet irradiation in a flow of oxygen. Some carbon-containing remnants, however, cannot be removed by this treatment.\(^{162}\)

OPTICLEAN™ (producer, Caliope; sold in Europe by Caliope Ltd, 3 Marfleet Close, Great Shelford, Cambridge CB25LA, UK, or by LOT, Im Tiefen See 58, 64293
Darmstadt, Germany) is a solution of polyurethane (PU) in a mixture of ethyl acetate, alcohol and water, which can be applied to plane surfaces like a lacquer. This polymer film can also protect from dust during sample storage, but not from humidity. Before measurements, the film is torn off and takes contamination with it. New surfaces which had no contact to air can be obtained by cleaving under inert liquids,\textsuperscript{169} \textsuperscript{168} cleaving in vacuum or ion sputtering.\textsuperscript{169} Argon ions (2–3 keV)\textsuperscript{170} or krypton ions (5 keV)\textsuperscript{171,172} can produce surfaces which are less contaminated than after cleaning with ultrasound or with polymer film.

### 3.2 Cross-sections of Coatings

To gain information on the nanostructure of the bulk of coatings by SPM, fracturing, ultramicrotomy, grinding and polishing, etching, replica techniques and ion beam sputtering can be employed.

Many coatings can be investigated after simple fracturing of notched bars.\textsuperscript{23,173–177} On notched glass bars, a fracture mirror of some square millimeters can be obtained, which is characteristic for the glass volume and oxidic vitreous or crystalline coatings. Thus, coatings with a thickness of more than some tens of nanometers can be investigated. A deep sawn notch is to be preferred to notching with a diamond, which produces more fine dust particles on the fracture surface (see Figure 10d).

Cross-sections can be produced by sandwiching two coated surfaces face to face or a coated sample to a dummy. For TEM investigations, Becker and Bange marked the surface of interest with an additional Cr coating.\textsuperscript{178} Wilder et al. imaged cross-sections of metal oxide semiconductor devices with AFM after sandwiching, sawing, lapping, polishing and selective etching.\textsuperscript{179}

Duparré et al. applied preparation techniques which have been developed for TEM for cross-sections of optical coatings and compared AFM and TEM images.\textsuperscript{180,181} 150 nm thick single and multilayers of MgF\textsubscript{2} and LaF\textsubscript{3} on Si were embedded in Araldite and fractured or ground, ion polished and ion beam etched. Fracturing resulted in too high steps between the Araldite and the sample, but in higher AFM resolution on single layers. The fractured triple layer was too rough for AFM imaging; it could be scanned only after ion polishing and ion etching. In both cases, the columnar structure of the fluorides was better made visible with TEM. Ion beam preparation of Mo—Ti and TiN hard coatings allowed similar results for imaging with TEM and AFM.\textsuperscript{182}

Ultramicrotomy\textsuperscript{178,183–185} and replica\textsuperscript{186} techniques have also been developed for imaging in electron microscopes and can also be used for SPM. Ultramicrotomes cut extremely thin slices with a diamond blade. It has been shown that this routine method for medical or biological materials can also be applied for oxidic coatings.\textsuperscript{176}

For the replica technique, a Pt–C and/or C film is evaporated on the sample surface (e.g. a fracture surface) and subsequently removed in water or acidic or alkaline solutions. Then the replica film is imaged instead of the sample itself. In contrast to replica coatings for TEM, which are evaporated with oblique incidence to render high contrast, replica coatings for SPM are evaporated vertically to avoid artifacts.\textsuperscript{187} Capillary forces between the SPM tip and the replica film, however, have been reported to alter the film topography during scanning.\textsuperscript{187,188} Soft samples can be shock frozen and fractured before replica preparation.\textsuperscript{187,188}

### 3.3 Fixation, Coated Fibers and Small Particles

With “stand-alone” scanning probe microscopes, many bulk samples can be investigated without cutting them into pieces; their sample holder is large enough for, for example, semiconductor wafers. In such microscopes, the tip is scanned instead of the sample, because of its smaller mass. In most commercial SPM instruments, however, the piezo drive is arranged as in Figure 2 and the sample holder is designed for samples with an area of around 1 cm\textsuperscript{2} and a thickness < 0.5 cm. Larger objects have to be cut.

With sufficient sample mass and a piezo design as in Figure 2, the specimen can just be laid on the sample stage. Light samples, which could be moved by the tip, need fixation. Flat samples can be fixed with double-sided adhesive tape to magnetic plates. For UHV or liquid cell applications, a glue must be chosen which does not contaminate the environment. In such cases, tailored clamps have proved to be reliable.\textsuperscript{189–191} Nonflat samples can be embedded in plasticine with the surface of interest parallel to the scanning plane.

For coated “small” particles such as fibers, grains or powder, adequate fixation must be tested. Double-sided tape does not always immobilize sufficiently and carries the risk of irreparable contamination of the tip. Indium is a very ductile metal. Pressing fibers into In foils with a stamp press has been shown to fix the fibers well and furthermore provides antistatic effects.\textsuperscript{8,192} Curtis Carter et al. recommend a carbon suspension in 2-propanol as a glue for fibers. This suspension is also used for electron microscopy and reduces charging.\textsuperscript{193} Other workers prepared fibers by fixing them to the sample platelet at two points at the ends.\textsuperscript{194,195} Embedding in resin as for electron microscopy and cutting and polishing or ultramicrotomy can provide information on fiber cross-sections.\textsuperscript{93,196–198} For the investigation of fully consolidated sol–gel coatings on glass fibers, however, a further preparation step was necessary: the coating thickness could be determined after mild etching with HF.\textsuperscript{194}
Solid grains with diameters between 20 and 70 μm have been fixed with gelatine; for small flat particles, drying a water suspension on microscope slides works well. Garcia and Edwards developed special sample holders for scanning individual particles with diameters between 70 and 500 μm. They drew fine glass pipets, which could be fixed on SPM sample holders and connected to a water jet pump.

3.4 Preparation for Scanning Tunneling Microscopy

STM is suitable only for conductive surfaces. For the investigation of nonconductive coatings or of cross-sections of conductive coatings on nonconductive substrates, AFM is recommended. If mainly surface features larger than 10 nm are to be expected, nonconductive samples can be coated with gold as for electron microscopy. Smaller details can be imaged only after special evaporation methods with cooled samples or on replicas.

4 ARTIFACTS AND CALIBRATION

All deviations of the measured profile from the true sample topography are to be considered as artifacts. Artifacts in SPM can be caused by

- the data processing;
- the measuring system;
- the tip geometry;
- the behavior of the sample during scanning. (See references 9, 42, 62, 204, 205.)

In many cases, combinations of these effects are observed. One impressive example is the SPM images of DNA strands on mica. The true diameter of DNA strands is 2.5 nm. On SPM images, an apparent height of 1 nm is measured. The apparent width is 15–20 nm in contact mode AFM under water, 5 nm in Tapping mode AFM under water (see section 2.4.5) and 3.5 nm in STM in humid air. The error in the height is ascribed to tip-induced deformation of the molecule and the error in the lateral dimensions is ascribed to the tip geometry and the interaction distance.

4.1 Data Processing and Measurement System

The most important issue in data processing is the applied filters. Not all types of representations (e.g. quasi-three-dimensional, top view, with color encoding height or in illumination mode) give similar evidence. Therefore, it is recommended to judge unknown surfaces from many different representation modes.

4.2 Tip Geometry

Tip geometry is the decisive detail of SPM. Because of the small range of near-field interactions, it is easier to gain high resolution on flat samples than to image rough samples truly. Artifacts result if the tip radius R is larger than the radius of curvature rS of surface features, but even at rS < 2R, tip convolution is essential. Diameters of single elevated objects are imaged too large and diameters of holes are imaged too small. In most cases, the height of single elevated objects is imaged correctly and the depth of narrow trenches and pores is underestimated.

SPM sensors can have fins or blunted tips if the holes in the etching masks used for tip production are not perfect squares. Fins result in an apparently preferred orientation (see Figure 9a–d). Measuring a sample with different tips or turning the sample can help to decide whether a preferred orientation is true or apparent.

At peaks which are narrower than the tip, the roles of object and probe are exchanged, and such peaks can be affected by external vibrations, feedback in the measuring system or wrong gains. For each scan, a new compromise of optimum scanning speed and gain has to be found. With low speeds, low gains can be realized. Because of thermal drift of the actuator, the speed should not be too low. Reasonable scanning frequencies are in the range ca. 20–1 lines s⁻¹. For large scans (100 μm²), low scanning frequencies are necessary; small scans can be executed faster.

The piezo actuators can affect images in the form of hysteresis, nonlinearity, thermal drift and creep. Single tube scanners do not scan an ideally flat surface, but move along a spherical surface. This nonlinearity can be removed with mathematical algorithms. For extremely flat samples, however, the angle between the sample surface and scanning plane is too small to be recalculated properly. Hysteresis artifacts are avoided by imaging only traces in one direction. Thermal drift decreases with running time and in well-conditioned air, but cannot be avoided totally in ambient conditions.

Creep means that the piezo material does not react instantaneously to voltage pulses and does not stop instantaneously after the voltage pulse. Therefore, dimensions can be wrong in the slow scanning direction (generally y) and overswinging can occur at steep steps. On three-dimensional representations, overswings give the illusion of additional peaks or troughs. On top-view images, overswings can enhance the contrast.

Piezoelectric materials age, especially when they are not used. At temperatures above 150 °C, they depolarize. They should be recalibrated from time to time and must be recalibrated after the baking of vacuum instruments (see section 4.4).

Images can be affected by external vibrations, feedback in the measuring system or wrong gains. For each scan, a new compromise of optimum scanning speed and gain has to be found. With low speeds, low gains can be realized. Because of thermal drift of the actuator, the speed should not be too low. Reasonable scanning frequencies are in the range ca. 20–1 lines s⁻¹. For large scans (100 μm²), low scanning frequencies are necessary; small scans can be executed faster.

The piezo actuators can affect images in the form of hysteresis, nonlinearity, thermal drift and creep. Single tube scanners do not scan an ideally flat surface, but move along a spherical surface. This nonlinearity can be removed with mathematical algorithms. For extremely flat samples, however, the angle between the sample surface and scanning plane is too small to be recalculated properly. Hysteresis artifacts are avoided by imaging only traces in one direction. Thermal drift decreases with running time and in well-conditioned air, but cannot be avoided totally in ambient conditions.

Creep means that the piezo material does not react instantaneously to voltage pulses and does not stop instantaneously after the voltage pulse. Therefore, dimensions can be wrong in the slow scanning direction (generally y) and overswinging can occur at steep steps. On three-dimensional representations, overswings give the illusion of additional peaks or troughs. On top-view images, overswings can enhance the contrast.

Piezoelectric materials age, especially when they are not used. At temperatures above 150 °C, they depolarize. They should be recalibrated from time to time and must be recalibrated after the baking of vacuum instruments (see section 4.4).

4.2 Tip Geometry

Tip geometry is the decisive detail of SPM. Because of the small range of near-field interactions, it is easier to gain high resolution on flat samples than to image rough samples truly. Artifacts result if the tip radius $R$ is larger than the radius of curvature $r_S$ of surface features, but even at $r_S < 2R$, tip convolution is essential. Diameters of single elevated objects are imaged too large and diameters of holes are imaged too small. In most cases, the height of single elevated objects is imaged correctly and the depth of narrow trenches and pores is underestimated.

SPM sensors can have fins or blunted tips if the holes in the etching masks used for tip production are not perfect squares. Fins result in an apparently preferred orientation (see Figure 9a–d). Measuring a sample with different tips or turning the sample can help to decide whether a preferred orientation is true or apparent.

At peaks which are narrower than the tip, the roles of object and probe are exchanged, and such peaks can be affected by external vibrations, feedback in the measuring system or wrong gains. For each scan, a new compromise of optimum scanning speed and gain has to be found. With low speeds, low gains can be realized. Because of thermal drift of the actuator, the speed should not be too low. Reasonable scanning frequencies are in the range ca. 20–1 lines s⁻¹. For large scans (100 μm²), low scanning frequencies are necessary; small scans can be executed faster.

The piezo actuators can affect images in the form of hysteresis, nonlinearity, thermal drift and creep. Single tube scanners do not scan an ideally flat surface, but move along a spherical surface. This nonlinearity can be removed with mathematical algorithms. For extremely flat samples, however, the angle between the sample surface and scanning plane is too small to be recalculated properly. Hysteresis artifacts are avoided by imaging only traces in one direction. Thermal drift decreases with running time and in well-conditioned air, but cannot be avoided totally in ambient conditions.
serve for imaging the tip. Images of steps which are steeper than the tip are convolutions of true surface profile and geometry of the contact area of the tip (see Figure 10a and b). Steep steps are imaged with the half apex angle \( \alpha \) of the tip (Si\(_3\)N\(_4\) pyramids: \( 2\alpha = 70.5^\circ \)). Cantilevers are installed in the scanning head with a flat angle of 10–20° with respect to the sample plane. Thus, e.g. cubes or spheres seem to be asymmetric.\(^{204}\)

Examples of multiple tips are given in Figure 10(c). The contact to the sample changes between the individual tips. Trenches between the crystallites of the SnO\(_2\) coating are imaged twice; all of the individual glass dust particles on the fracture surface of Figure 10(d) seem to have the same shape (small particles are oblong, large particles seem to be double). In Figure 10(e), a gold coating which is used for SEM is scanned by AFM with a multiple tip: the metal grains resemble berries. So-called ‘ghosts’ appear if the contact changes from one tip flank to the other in narrow holes.\(^{213}\)

Schwarz et al. compared tips from different suppliers and stated that Si\(_3\)N\(_4\) pyramids with a relatively low aspect ratio are to be preferred for unknown samples.\(^{62}\) They
Figure 10 Imaging the tip: (a) tin oxide coating on glass with a defect that is narrower than the tip; (b) fracture surface of SnO$_2$-coated glass: the coating surface is imaged by the flat side of the tip; (c) a multiple tip images the trenches between the SnO$_2$ crystallites twice [same sample as (a)]; (d) fracture dust particles on the glass surface are also imaged twice by a multiple tip; (e) 'berry'-like appearance of the grains on a gold coating for SEM, due to a multiple tip.
have the advantage of a well-defined geometry with small deviations. They are harder than Si tips and perform well on rough samples, with high scanning frequencies and large scanning areas. Etched Si tips are sharper, but exhibit larger variations; they are more sensitive to damage and tend to develop multiple tips. This makes it harder to recognize tip defects.

### 4.3 Sample Response

It can be difficult to scan extremely rough samples. If there are elevations higher than the tip (Si$_3$N$_4$: about 3 $\mu$m), the cantilever bar touches the sample and the image shows a flat plane. Contamination particles or parts of soft samples can stick to the tip and let it appear blunt; abrasive surfaces also affect the tip quality during scanning. Strong local variations of interaction energy can convolute with real topography. On polymers and other organic substances, it can stick to the tip and let it appear blunt; abrasive surfaces can be understood. For many materials give rise to a marked onset overswing (see Figure 11) during scanning in a humid environment. This overswing is due to the acceleration of the water layer on the sample at the start of each scan line. Products of reactions with the environment and contamination can also affect the images.

The following nine rules are recommended for avoiding artifacts as far as possible:

- know the artifacts to which your system is prone;
- use different tips;
- take images with different sample rotation;
- rotate the scanning direction;
- change the scanning velocity;
- change the scanning area;
- compare with other imaging techniques;
- represent images with as few filters as possible;
- keep in mind that there are as yet no commonly accepted standards for product claims.

### 4.4 Calibration

For the use of SPM as a reliable metrological technique for coatings, piezos and tips must be calibrated taking into account artifacts and systematic errors. Unknown variables for the deconvolution of SPM images are:

- sample geometry;
- tip geometry;
- contact area;
- local variations of interaction;
- piezo behavior.

Theoretical deconvolution calculations exist for STM and AFM images with atomic resolution, even for multiple tips, but there is no standard routine which is valid for all surfaces and tips. A rather laborious way of eliminating one of the unknown variables is to scan a used tip with a new one. Michely et al. combined STM with FIM to provide in situ analysis of the tip. Usually, standard samples with known surface features in the nanometers to micrometers range are imaged. One can exploit the effect of reversed imaging: objects which are smaller than the tip give information on the tip geometry. Calibrations must be performed for each scan area and scanning velocity.

For small scans, the $x$ and $y$ axes can be calibrated with the help of atomically resolved images of known crystal lattices such as highly oriented pyrolytic graphite (HOPG), Si or mica. The parameters for the $z$ height of atom images, however, are not yet fully understood. For $z > 10$ nm, commercial profiler standards are available. Standards for electron microscopy, e.g. latex spheres, have dimensions of some tens of nanometers. Some authors proposed polystyrene and latex spheres (diameters 10–40 nm) on mica, or etch InP columns or used well-known coatings such as SnO$_2$ or Cr. Structured wafers from chip fabrication or diffraction gratings serve for scan areas $xy > 1 \mu$m$^2$. For topographic features of the order of nanometers, test methods are under development. For full characterization...
of the tip geometry, not only the dimensions of standard topographies are important, but also their geometrical form, e.g. angles of inclination and radii of curvature.

Standard samples with steep parallel ripples can be obtained from SrTiO$_3$ crystals. On the (305) surface, steps of about 10 nm height are observed. Commercial standards are Nanoedge by IBM with parallel ripples or Si grid with pyramid holes, which are produced with similar processes to the tips (by Digital Instruments, see Figure 12a and b). The tip radius itself cannot be determined exactly, as the apex radii of the etch holes are of the same order.

In some cases, SPM is combined with SEM, so a direct SEM imaging of the SPM tip can be achieved. Transfer of the tip to an external microscope bears the risk of contamination or destruction. Periodical tip tests on well-known surfaces are recommended; tests before and after the imaging on unknown samples can give hints on wear-induced tip blunting.

5 APPLICATIONS

In the following sections some practical examples are given of coating questions such as nucleation, defects, roughness, thickness, microstructure, crystal phases, homogeneity, interfaces, porosity, adhesion, hardness, scratch resistance, tribology, wear and corrosion, which can be solved with the help of SPM.

5.1 Nucleation, Oxidation

For the investigation of film nucleation, flat substrates with well-defined surfaces must be chosen. As there is no possibility of chemical identification, substrate irregularities, contaminants and nuclei must be identified by careful investigations of the substrate before coating. Early stages of the growth of metal films on glass were investigated by SPM by Duyne et al., Roark and Rowlen, Smith et al., and Creuzet.

5.1.1 Silver on Glass: Silver Island Films

The first steps of sputtering Ag on glass display Vollmer–Weber growth (three-dimensional growth of islands) and the islands are much larger than during evaporation. A thin physical vapor deposition (PVD) silver island film (AgIF) consisting of flat, spheroidal islands with dimensions below 100 nm and an equivalent layer thickness of some nanometers is used as a substrate for surface-enhanced Raman spectroscopy (SERS). SERS is an extremely sensitive method for identifying adsorbates and provides information on their binding, orientation and dynamics with an information depth of about 10 nm. SERS is restricted to surfaces with a well-defined roughness. The analytical relationship between the roughness and the surface enhancement factor is not yet fully understood. With AFM, the roughness of AgIFs could be characterized over the whole range of wavelengths. Histograms of different AgIFs showed a Gaussian distribution of the island radius, the ratio of radius to height decreasing with increasing radius. The direct determination of this ratio facilitated the interpretation of the measured SERS enhancement factors. A tip convolution was not considered, although with particle radii of 10–100 nm and tip radii of 20–50 nm tip artifacts
cannot be ruled out. Different optical properties of AgIFs on microscope slides with and without a Formvar coating (polyvinyl Formvar solution, trade mark by Monsanto) were not caused by different particle radii, but only by smaller heights of the islands on the uncoated glass.\cite{229}

5.1.2 Gold

The dimensions and the shape of the first nucleated islands are responsible for the film roughness in the subsequent growth steps, when the coverage becomes complete. This was shown by Vancea et al. with the help of STM images of PVD Au films on Corning 7039 glass, Si(100) and freshly cleaved NaCl.\cite{234} These films completely cover the substrates if the thickness exceeds 8–12 nm. On the cleaved crystals, the films were much smoother than on glass and Si, with height differences below 0.1 nm. On HOPG, even 80-nm thick gold layers were still extremely smooth, displaying regular hillocks with the periodicity of the C atoms of the substrate (0.29 nm). On Corning 7039, the hillocks had diameters of 20–40 nm and height differences of 6–17 nm. On Si(100), they were even larger. The distinctive island growth on Si was explained by gold silicide nuclei on which pure gold can grow. The role of the number of such nuclei where tight bonds to Au adatoms can be established was revealed by a Corning 7039 substrate, on to which <1.5-nm Cr was evaporated before the Au coating. Cr offered a higher number of stable nucleation centers and thus led to a smooth Au film with height differences of 2–3 nm.

5.1.3 Silicon: Amorphous and Crystalline Islands

The first phases of layer growth of microcrystalline Si (µc-Si) from a plasma-enhanced CVD process are strongly dependent on the substrate type. Smith et al. investigated the growth of µc-Si for thin-film transistors on crystalline Si and on polished glass with AFM.\cite{231} After a deposition time of 15 s, the first Si islands on glass with an equivalent film thickness of 1.5 nm appeared less uniform and flatter than on Si. After 1 min, at an equivalent film thickness of 5 nm, the film on Si showed complete coverage. After 5 min, at 30 nm, the differences between the two substrates disappeared. Reflection high-energy electron diffraction (RHEED) measurements confirmed that at an equivalent film thickness of 4–5 nm, amorphous a-Si transforms to randomly oriented µc-Si. The island shape suggested three-dimensional growth on Si and a more two-dimensional character on glass. The inhomogeneous appearance of the Si islands on glass is considered to be due to selective erosion of nuclei with highly stressed bonds during plasma CVD.\cite{231}

5.1.4 Surface Oxidation

One of the reasons for the development of AFM was the wish to pursue surface oxidation on an atomic scale. STM had already rendered images of the first stages of oxidation of Ni, Si and Al.\cite{235–237} On Mg, oxide layers with a thickness of up to 2.5 nm could be investigated via STM;\cite{238} MgO grew in domains with diameters of 2–6 nm.

In contrast to STM, AFM allows imaging not only of oxidized islands, but also of totally covering oxide layers. On AFM images with atomic resolution, a 2.3-nm thick natural oxide layer on Si(111) displayed 0.05-nm high regular waves resembling the crystalline structure of Si.\cite{236} Images with lower resolution showed hillocks with diameters of about 40 nm and height differences < 1 nm.\cite{239}

Surface reactions such as oxidation give rise not only to roughness changes, but also to changes in the measured forces (see section 5.5.4).\cite{229}

5.1.5 Island Growth of Self-assembling Organosilanes

n-Octadecyltrichlorosilane (OTS) tends to form islands\cite{237,240} before a molecular layer is closed. AFM served for determining the number, width and height of these islands. According to Fourier transform infrared (FTIR) spectroscopy, OTS develops a 2.6-nm thick, closed monomolecular film on float glass after an immersion time of 90 min.\cite{240} This finding was supported by AFM measurements. After immersion times of <90 min, individual islands with a height < 2.6 nm emerged. The height, which was less than the thickness of one monolayer, was explained by the lower order of the molecular chains. After longer immersion times, the roughness increased from the minimum of \( R_{\text{a}} = 0.07 \) nm at 90 min because of individual islands with low orientation on the first oriented covering monolayer. FTIR measurements give average values over some surface layers and could not resolve the local arrangement of ordered monolayers and islands with low order.\cite{240}

In contrast to OTS, octadecylsiloxane (ODS) submonolayers show two types of growth: an island-type growth with roughly vertically aligned hydrocarbon chains and formation of disordered, liquid-like submonolayers.\cite{241} Which type of growth prevails depends on the relative coverage and other preparation parameters.

5.2 Surface of Coatings: Defects, Roughness

5.2.1 Defects: Holes and Cracks

Figure 13(a) and (b) gives an example of the capability of defect detection with AFM. An Fe\textsubscript{2}O\textsubscript{3}·SiO\textsubscript{2} sol–gel dip coating was applied on alkali silicate glass without
a coupling agent.\textsuperscript{242,243} The sample appeared homogeneous under an optical microscope, but AFM revealed partially uncovered substrate. The glass could clearly be discerned from the coating because of the polishing grooves. With an adequate coupling agent, no such holes were detected.

Submicrometer defects in a sol–gel coating are displayed in Figure 14. A sol–gel dip coating of STZ was heated to 200 °C within 45 min and then investigated by secondary neutrals mass spectrometry (SNMS).\textsuperscript{245} By sputtering with Kr ions for 330 s, 60 nm of the 90-nm thick coating were removed. The sample was then transferred into a contact mode AFM instrument to investigate the sputtering crater. The topography of the sputtered crater is homogeneous with a few exceptions: in the top right corner a small pore with a diameter of 40 nm and a depth of 2 nm is detected. The large pore with a diameter of 300 nm is most probably due to an interfacial bubble and was partially opened by the AFM tip.

Figure 15 displays a coating system with a mismatch in thermal expansion.\textsuperscript{177} The conductivity of ITO, (In\textsubscript{2}O\textsubscript{3}/SnO\textsubscript{2}) coatings is affected by Na\textsuperscript{+} diffusing from the substrate glass into the ITO. The charge carrier concentration is reduced by this contamination. Fused silica would be a good substrate material because of its purity. The thermal expansion coefficient of fused silica ($\alpha = 0.5 \times 10^{-6} \text{ K}^{-1}$), however, is much smaller than that of ITO ($\alpha = 7.2 \times 10^{-6} \text{ K}^{-1}$). ITO is applied at elevated temperature and during the cooling the coating cracks, so no homogeneous products can be obtained.\textsuperscript{246}

Commercial glass containers are coated with an oxide (SnO\textsubscript{2} or TiO\textsubscript{2}) and an organic protection (waxes or polyolefins) against friction and wear. Figure 16 displays the surface of a green bottle with defects in the organic coating.\textsuperscript{8} These rectangular and triangular flat holes are presumably due to NaCl crystals originating from the oxide coating. The oxide coating is applied by pyrolysis of, e.g. SnCl\textsubscript{4} before the annealing lehr. Sodium from the glass can react with the chloride and the resulting salt crystals fall off and leave 12 ± 0.5 nm deep holes in the second coating.
5.2.2 Roughness

Roughness values measured by SPM can be too high if the instrumental noise is too high and too low if the tip is blunt. For credible measurements, optimum resolution and low noise are necessary. If both are guaranteed, AFM can measure roughness even below RMS = 0.1 nm on areas in the square micrometers range on polished surfaces and films.\(^{1145}\) (All RMS values in the following text are valid for areas of square micrometers unless stated otherwise).

For the miniaturization of semiconductor devices, removing the uncontrolled oxidation layer is decisive. Especially the roughness after wet chemical or plasma etching is important. AFM roughness measurements help to improve the etching processes.\(^{239,247}\)

During production of metal oxide semiconductor components, the natural oxide is removed by HF etching before the controlled growth of the gate oxide. On the natural oxide on Si(100) and Si(111), Crossley et al. measured RMS = 0.8 and 1.4 nm, respectively\(^{247}\). HF etching increased the roughness to RMS = 1.2 and 1.8 nm, respectively.

A much lower roughness of RMS = 0.1 nm was found for the natural oxide layer on Si wafers by Duparré and Jakobs\(^{181}\). They detected a similar roughness on superpolished fused silica. In addition to SiO\(_2\), also 500–1200 nm thick borophosphosilicate glass (BPSG) CVD coatings are used as isolators in integrated circuits. The roughness of these coatings first increases with increasing thickness and then reaches saturation at RMS = 18 nm\(^{248}\). Subsequent densification of the coatings at 850 °C reduces the roughness back to RMS = 2 nm. Such smooth surfaces are desired for the detection of unwanted defects smaller than 0.2 \(\mu\)m.

5.3 Thickness

In some cases, coating defects such as holes or scratches can help to measure the thickness without any further preparation (see e.g. Figure 19 section 5.4.1). If the nanostructure of the coating and substrate allow the detection of the interface, thickness can be measured on AFM images of fracture surfaces.\(^{23,174,246}\) One advantage over conventional thickness determination methods is the high lateral resolution which permits the detection of local thickness variations and measurements with difficult sample geometry.

Yoshino coated float glass partially with fluoralkyltriethoxysilane.\(^{249}\) At the boundary with the uncoated glass, the exact thickness of the coating could be measured to be 6 and 9 nm, which correspond to two and three molecular layers, respectively.

The easiest way to measure the thickness of sol–gel coatings is to make a scratch with a plastic blade, immediately after coating in the soft layer. After annealing, the densified gel can be investigated in a mechanical profiler. An AFM image of such a scratch is displayed in Figure 17. A float glass dip coated with
Figure 17 Fracture surface of float glass with a 300 nm thick sol–gel coating.8 The STZ dip coating was scratched with a plastic knife, heated to 100 °C, notched and fractured for imaging the fracture mirror in the AFM instrument. The interface between the not fully densified film and the glass is clearly recognizable and allows thickness determination.

STZ was scratched with a plastic blade, heated to 100 °C, notched and fractured. Such coatings are not yet fully densified and do not withstand mechanical profilometry. AFM images help to monitor the thickness changes during consolidation even at temperatures as low as 100 °C. The STZ coating in Figure 17 is 300 nm thick.

Samples with a difficult geometry for the determination of coating thickness include fibers. Röder developed a preparation method for cross-sections of sol–gel–coated glass fibers.184 She embedded STZ-coated Cemfil glass fibers in Araldite and sawed and polished the samples perpendicular to the fiber axis. Polishing contaminants and Araldite on the fiber cross-section were removed by 5–10 s of etching in 0.5% HF. The HF etching rate of Cemfil is higher than that of STZ, so the coating can be visualized as an elevated wall around the fiber (see Figure 18). The AFM measurement supported the assumption that similar sol–gel coatings on glass fibers are thinner than adequate coatings on flat substrates because of the lower roughness and surface tension of the fibers. In the case of the STZ coatings, the difference amounts to 15%.194,250

5.4 Microstructure and Nanostructure

5.4.1 Crystal Phases, Homogeneity

ITO coatings have great commercial significance as transparent conducting electrodes, e.g. for flat panel displays. The crystal phases of ITO from different coating methods have been observed with SPM by several workers.177,189,246,251–255 STM and AFM helped to understand that below a nominal thickness of 20 nm epitaxial ITO does not yet cover the substrate glass, but forms connected islands.253

ITO can be sputtered with metal (ITOme) or oxide targets (ITOox). On ITOox SPM reveals a homogeneous surface with columnar growth of one type of crystal. The lower conductivity of ITOme was shown to be due to an inhomogeneous microstructure of columns perpendicular to the surface, oblique columns and large, flat grains.189,255

ITO from the sol–gel process resembles the ITOox sputtered type, with a homogenous surface. The columnar growth can be seen on the scratch in Figure 19. The representation exaggerates the columnar character of the crystallites. Their average diameter is 25 nm and the
Figure 19  Scratch in a 50 nm thick ITO sol–gel coating with columnar crystal growth\cite{177,246} (the height: diameter ratio of 2:1 is exaggerated by the representation).

The height of most of the columns is equal to the coating thickness of 50 nm\cite{177,246}.

Figure 20(a–d) shows ITO sol–gel coatings annealed at different temperatures. Between 250 and 400°C, crystallization starts and the average diameter of the crystals increases from 20 nm at 400°C to 35 nm at 500°C. Homogeneity and crystal diameters are two of the important parameters for the conductivity of the semiconductive coating materials.

The crystallization of ITO coatings was also pursued with AFM\cite{177,246}. The crystal phase was identified by X-ray diffraction (XRD) and AFM served as a fast method to measure the growth of the crystallites. Figure 20(a–d) shows ITO sol–gel coatings annealed at different temperatures. Between 250 and 400°C, crystallization starts and the average diameter of the crystals increases from 20 nm at 400°C to 35 nm at 500°C. Homogeneity and crystal diameters are two of the important parameters for the conductivity of the semiconductive coating materials.

The ideal SnO₂ concentration for ITO coatings is about 10\%\cite{246,253,256,257}. At 14\%, the solubility of SnO₂ in the In₂O₃ lattice is exceeded. On AFM images a larger amount of small crystals is detected, which can be correlated with metallic Sn in the XRD spectra\cite{246}.

The performance of scratch-resistant Al₂O₃ sol–gel coatings is dependent on the crystallization of α-Al₂O₃ (corundum)\cite{258}. The best results were achieved with 70 nm thick cryptocrystalline coatings from alkoxide solutions. These coatings were too thin for XRD analysis. The coatings were optimized by comparing AFM images...

(a) Appears vitreous; on (b), (c) and (d) the average diameter of the crystals is 20, 25 and 35 nm, respectively.
with those of $\alpha$-Al$_2$O$_3$ coatings which were thick enough for identification of crystal phases by XRD. AFM images of the optimized coatings displayed the same morphology.

Another example of the complementary information obtained by XRD and AFM is the investigation of lead titanate coatings by Lai et al.$^{259}$ All coatings annealed above 300 °C displayed crystal peaks in the XRD spectra. In contrast, the AFM images displayed the typical pattern of vitreous coating even after annealing at 400 °C. On samples annealed at 450 °C, the AFM revealed crystallites which grew through the thin superficial vitreous film on the coating surface. Hence both the phases and their local distribution could be made clear.

5.4.2 Correlation of the Topography of Coatings and Substrates

Meyer et al. investigated the dependence of the topography of TiO$_2$ and Ta$_2$O$_5$ coatings on the substrate and the coating process.$^{260}$ Electron microscopy of cross-sections had given hints on differences before, but AFM resolved details much better. It was shown that the Ta$_2$O$_5$ coatings grow mainly in a two-dimensional manner and hence replicate the original substrate topography. TiO$_2$ coatings cover the polishing traces and develop a microstructure which is independent of the substrate. In spite of the thickness of 100 nm, the roughness of the Ta$_2$O$_5$ coatings, RMS $= 1$ nm, was similar to the polished optical glass substrate. The TiO$_2$ coatings displayed RMS $= 4.6$ nm (ion plating) and 7.7 nm (reactive evaporation). The last, high value is presumably caused by the columnar growth of the crystalline layer even in the first stages.

MgF$_2$ is also an optical coating with pronounced columnar growth. This had been shown by TEM images of replicas before.$^{261}$ The exact determination of crystallite diameters and roughness was possible only by AFM.$^{161,180,181}$

5.4.3 Interfaces

Cross-sections of coatings with good adhesion to the substrate can easily be imaged on fracture surfaces. The coating itself can only be recognized on AFM images if the fracture morphology is different from that of the substrate.

One example of such a coating is SnO$_2$ on glass, which serves for insulating windows (see Figure 10a–c and Figure 21a). The interface line is dominated by the shape of the crystals. The shape of the crystal grains is represented truly, in contrast to TEM images of ultramicrotome cuts. On those images,$^{185}$ the crystals appear with a slim columnar shape because of a preparation artifact and the grooves between the grains on the surface are not resolved because of the integral image of a slice. Ultramicrotomy tends to disguise grain boundaries, especially of coatings with low relative density.$^{178}$

In contrast to the AFM images, TEM images of ultramicrotome cuts reveal an interface layer between tin oxide and glass. This hydrosilicon type of interlayer is applied to prevent iridescence and as an Na$^+$ diffusion barrier. On TEM images, it appears similar to the vitreous substrate, but brighter.$^{185}$

The sample in Figure 21(b) is an SiO$_2$ sol–gel coating. After annealing at 500 °C for 1 h, the microstructure of the coating is similar to that of fused silica; the fracture surface resembles that of the float glass and the interface is barely visible.
Statthatos et al.\textsuperscript{262} and Liu\textsuperscript{177} showed with the help of AFM that thicker sol–gel coatings of TiO\textsubscript{2} and ITO which are manufactured by multiple dipping are homogeneous. In the coating volume, no interfaces or inhomogeneities were found at the boundaries of the single layers.

5.4.4 Porosity

AFM images of porous materials do not give the same three-dimensional impression as TEM images with extremely high resolution, because the AFM tip cannot see “inside” the pores. The literature contains examples of AFM images of porous material\textsuperscript{263–268} and of TEM images\textsuperscript{269,270} while a comparison of the two is also available.\textsuperscript{271} Generally, the actual radius of the AFM tip is unknown, and therefore the lower detection limit for small pores is also unknown. Typically, this radius is >10 nm. On conductive coatings such as porous Si, fine STM tips can detect pores with radii of 1–2 nm.\textsuperscript{272}

The rougher fracture surface of the STZ sol–gel coatings in Figures 17 and 22 is due to the porous microstructure of not fully consolidated gels. AFM images can help to pursue microstructural changes after different steps of consolidation. In STZ, even after annealing at 500 °C for 1 h, the pores remain. Figure 22 shows clusters, rings and linear alignments of particles with diameters of 70–400 nm in such a consolidated 1 μm thick coating.\textsuperscript{23}

Pore diameters can only be estimated to be in the same range. For exact values, the tip radius must be determined independently.

In contrast to STZ, fractured dense SiO\textsubscript{2} sol–gel coatings from tetraethylorthosilicate (TEOS) show a hillock pattern similar to the pattern of the substrate glass, and the interface is barely visible. Vong and Sermon investigated porous SiO\textsubscript{2} coatings from silica sols with different diameters of the colloidal particles.\textsuperscript{271} Sols with colloidal particles with average diameters of 17 nm resulted in porous coatings with particle diameters of 25–30 nm. In porous coatings from sols with average diameters of 100 nm, the particle coating did not change during annealing.

AFM investigations supported other measurements of the development of crystal phases and optical properties of TiO\textsubscript{2} coatings during annealing.\textsuperscript{273} Martin et al.\textsuperscript{273} coated fused silica and Si(100) via magnetron sputtering and annealed the TiO\textsubscript{2} coating for 1 h at different temperatures. Up to 700 °C, the hillocks with diameters of 40–50 nm did not change much. Between 300 and 700 °C, the roughness decreased from RMS = 4 to 3 nm, which correlated with a densification of the porous coating and index increase. Rutile crystallization causes dramatic topography changes from 700 °C on. Crystal facets developed, diameters increased to 100–200 nm at 900 °C and >500 nm at 1100 °C and roughness increased to RMS = 20 nm at 1100 °C.

5.5 Mechanical Properties of Coatings

5.5.1 Friction and Wear of Magnetic Storage Media

Customer magnetic storage media consist of an Al–Mg alloy substrate disk with a hard coating of Ni–P, the magnetic film (e.g. Co\textsubscript{79}Pt\textsubscript{14}Ni\textsubscript{7}) and a top coating. Special glass or glass ceramic disks are suggested instead of the metal alloy because of their smoother surface and higher temperature and shape stability.\textsuperscript{159} They can be manufactured with higher data density and lower thickness. Especially for small, hard disks and portable computers, glass disks are already used. Bhushan et al. compared the friction and wear of commercial hard disks of Al–Mg and glass and of laboratory glass ceramics and established parameters for a convenient determination of roughness.\textsuperscript{159,160}

As the distance between the hard disk and recording head is to be reduced from >50 nm to <25 nm, each single high protrusion is detrimental. Therefore, the highest z elongation is important in addition to RMS and correlation length. The adhesion forces due to the meniscus of lubricant between the recording head and disk and the friction were higher for rougher samples. Wear was dependent on the top coating and the environment. The durability of common carbon top coatings is reduced by moist or O\textsubscript{2}–containing atmospheres. The glass disks were protected with sputtered SiO\textsubscript{2} with higher durability, which is even improved by a humid atmosphere.
5.5.2 Wear Tests of Hard Coatings

Oberländer et al. used AFM to investigate the wear processes of hard coatings of TiN and partially oxidized TiN$_x$O$_y$ during friction against steel.\cite{274} The most important damage to the harder TiN coatings were scratches and delamination, caused by oxidized spots.

The scratch resistance of $\alpha$-Al$_2$O$_3$ hard coatings on float glass was investigated with the help of AFM by Hauk et al.\cite{258,275} A scratch tester, which simulated the load on windscreens by dirty wipers, moved a quartz grain with a constant velocity of 2 cm s$^{-1}$ and constant loads up to 100 g across the samples. Figure 23(a) and (b) displays AFM force mode images of scratches with a load of 100 g on normal float glass (Flachglas, Weiherhammer, Germany) and on a 70-nm thick alkoxide gel coating prepared from aluminum butoxide. The scratch on bare float glass is about 60 µm wide. In the trace, stripes of undamaged glass and grooves are found; most of the damage is due to prominent stripes of material dragged out of the surface. These up to 1.2-µm high elevations cause stray light on degraded windscreens. On the coated part of the sample, the scratch can only be detected by AFM. The width of the trace is about the same, but the elevations of <20 nm do not interfere with visible light.\cite{174,258}

5.5.3 Tribology of Carbon Coatings

Snitka et al. produced 180–360 nm thick C coatings on Si, GaAs and fused silica via electron beam evaporation.\cite{276} With ion beam support, the coatings became DLC; without ion beam support, porous non-crystalline a-C developed. AFM served for the estimation of surface energy from the tip adhesion and for the judgement of the scratches from two tribological tests (diamond tip on plate and steel ball on plate). The two tribological tests caused different damage to the a-C coating on Si(100). The diamond tip produced traces typical of plastic behavior; under the steel ball, the coating delaminated as one would expect for a vitreous material. The DLC coatings proved to be much more scratch resistant than a-C. On a-C–Si an adhesion of 1.8 nN was measured, on DLC–Si values of about 20 nN were found and on DLC–fused silica the adhesion amounted 76 nN. The surface energy was estimated to be 6 mJ m$^{-2}$ (a-C–Si) and 68 mJ m$^{-2}$ (DLC–Si, DLC–GaAs), with an estimated tip radius of roughly 50 nm. On DLC–fused silica, a jump to contact occurred at a distance of 20 nm, which was a sign of a liquid capillary bridge of adsorbed water; the surface energy was estimated to be about 120 mJ m$^{-2}$.

5.5.4 Atomic Force Microscopy Tip Adhesion as a Hint to Chemical Modification

Friedbacher et al. measured the roughness of differently pretreated Si substrates and the pull-off force of the AFM tip.\cite{239} The removal of the oxide layer resulted in a lower pull-off force: on the natural oxide layer, this force was 2 nN, and after etching in an H$_2$ plasma or in HF, it decreased below 0.5 nN. The force–distance curves allowed conclusions on the species on the surface. The bias treatment in hydrogen created an H-terminated surface; in a mixture of hydrogen and methane, SiC was found.

Kiridena et al. removed the hydrosilicone film partially with the AFM tip and measured the Young’s modulus.
of film and substrate. The result, which contrasts with experience in the macroscopic world, is explained by the fact that modulus measurements via phase shift are sensitive only to the first atom layers. In air, mica is covered with a water film, which is detected by force modulation instead of the mica. With butanol as environment, the measured Young's modulus of mica was higher than that of the hydrosilicone. With increasing modulation amplitude, the modulus increased to values close to the bulk values.

5.5.5 Peeling Tests

AFM improves conventional peeling tests. The decision as to whether a fracture is adhesive or cohesive depends on the detection of small remnants on the surface, which is better performed with a high-resolution method such as AFM. Creuzet et al. aged a compound of float glass and PU and analyzed the glass after the peeling test. The aged elastomer delaminated cohesively. However, also without any aging, 20-nm high polymer particles with diameters of 80 nm were found on the glass surface after delamination. These hillocks were identified to be different from the glass composition by force–distance curves. From these results, it can be concluded that the delamination takes place in an interface layer in the PU which had been damaged by ion migration from the glass surface. The hillocks are interpreted as PU fibrils which developed during the peeling, fractured and collapsed on the glass surface.

5.6 Corrosion and Aging

Crystallization and corrosion of sol–gel coatings of TiO₂ and in the system Al₂O₃ · TiO₂ · SiO₂ were investigated with AFM by Du et al. In both cases, the corrosion behavior depended on the crystal phases. The roughness of Al₂O₃ · TiO₂ · SiO₂ increased gradually with time after treatment in 1 M NaOH at 60 °C, and the sensitivity to scratches by the scanning tip also increased. According to their shape, the crystallites which developed during corrosion could be divided into three groups. At high TiO₂ contents, quadrangles with the habit of anatase developed, presumably by precipitation from the solution. At an Al₂O₃ · TiO₂ · SiO₂ molar ratio of 1:2, hexagonal crystallites were found, which could be due to nepheline. On coatings with other compositions, irregular hillocks without any crystal facets could not be correlated with a distinct crystal shape.

Helsch investigated the aging of porous SiO₂ anti-reflective coatings in different media. The chemical processes were analyzed by SNM and the habit and distribution of reaction products on the surface were imaged by AFM. Beside other reactions, the long-term transmission losses of the 100-nm thick coatings in normal air were found to be due to 500-nm thick individual crystals on the surface, consisting of CaCO₃. The large inner surface of the coatings allowed Ca²⁺ diffusion from the substrate glass to the surface, where Ca²⁺ reacted with CO₂.

MICROSCOPY OF COATINGS

The interaction of the magnetic moment of an atomic nucleus with a static magnetic field gives rise to nuclear magnetic resonance (NMR). Examination of NMR can reveal both the chemical structure and physical characteristics of a chemical system and this makes the technique particularly useful for the study of materials such as those encountered in coating and adhesive applications. No other spectroscopic technique can offer such a detailed description, both qualitative and quantitative, of molecular structure, including features such as stereochemistry, reaction kinetics and surface phenomena. Each nucleus has a distinct precession frequency, allowing different (e.g. $^{13}$C, $^1$H, $^{29}$Si) to be observed within a sample. The technique does, however, suffer from a few drawbacks. First, it is not a particularly sensitive technique, and it is most readily applied to features that constitute at least a few percent of the sample. Second, sample preparation can be difficult; this can be especially true for coatings and adhesives materials, as will be discussed. The most detailed chemical information is obtained from the spectra of liquids or solutions, which precludes cross-linked or cured materials. The spectra of solids, including cross-linked and cured materials, must be studied using complex experimental approaches, and these often suffer from poor resolution.

1 INTRODUCTION

Because of the various functions they serve – mainly decorative or protective – coatings can be quite complicated formulations that must form a strong bond with the surface to be covered (the substrate). In general, coatings are composed of a binder, which originates as, or becomes, a polymer. A volatile solvent mixed with the binder lowers the viscosity enough to allow the coating to be spread evenly across the substrate. Finally, additives such as pigments, opacifiers, drying agents, and dispersants may be included in the formulations to achieve a desired color, intensity, or other effect. Some coatings form a film over the substrate when the solvent evaporates. A latex is water based, although organic solvents are used in other applications. The polymer component is usually a vinyl or acrylic polymer, or a cellulose derivative; in other formulations, the coating forms when monomeric binder molecules polymerize (1–34). The monomeric binders are usually based on alkyds, epoxies, unsaturated polyesters, or vegetable oils. Oxidation of metal surfaces creates yet another class of coating. Adhesives (3–9, 15, 25–28) are related to coatings in that they are also thin films in which effective bonding, in these cases between two substrates, is required. In pressure-sensitive applications, the adhesive is inherently sticky and bonds after moderate stress is applied; such adhesives are usually removable. Reactive adhesives, such as epoxies, rely on chemical reactions, which are often similar to those involved in coating formation. Materials commonly used as adhesives include the vinyl polymers, acrylates, and cyanoacrylates [(1–34) in Table 1] in addition to the epoxy resins.

2 ANALYSIS WITH NUCLEAR MAGNETIC RESONANCE

The phenomenon of NMR arises from the interaction of an atomic nucleus’ magnetic moment with a static magnetic field. The magnetic moment precesses (rotates)

about the static field with a frequency, the Larmor frequency \( (\omega_0) \), that is a property of a given nuclide. Smaller frequency variations called chemical shifts \( (\delta) \) depend on the exact chemical structure around a particular nucleus. Other features of this precessional motion, such as the coherence of the moments, provide information about molecular reorientations; these relaxation times can be used to calculate motional frequencies and activation energies. No other spectroscopic technique can offer such a detailed description of molecular structure, including stereochemistry, reaction kinetics, and surface phenomena. Because distinct nuclei exhibit separate precession frequencies, in many cases several different nuclei within a sample can be independently observed (e.g. \( ^{13}\text{C}, \ ^{1}\text{H}, \text{ and } ^{29}\text{Si} \)) and may provide complementary information. NMR experiments have even been designed so that two or more nuclear properties can be correlated and compared.

While NMR is not the most widely used technique for the study of coatings, it can provide useful information in many cases. It is, in particular, well suited for elucidating the chemical structure of a coating or adhesive formulation before application and can often provide a fairly complete description of the material’s composition. For example, poly(n-butyl methacrylate-co-isobutyl methacrylate) [9011-53-4] is often used as a pressure-sensitive adhesive; part of its \( ^{13}\text{C} \) spectrum is shown in Figure 1. The resonances owing to each comonomer can be clearly identified; if the experimental conditions are appropriately set, the relative amounts of each can be easily calculated based on a comparison of peak areas. Such quantitative compositional analyses can be readily done for many polymer types.

Adhesives and coatings that solidify through a network-formation reaction, such as epoxies, usually cannot be dissolved in their final state (although the original constituents can be), and such materials must be studied as solids. The mechanisms and kinetics of the reaction can be characterized, and intermediate species identified in some systems. Because of the limited sensitivity of NMR, such studies are usually performed on samples of the coating or adhesive alone, although the substrate can be included in some cases.

The efficacy of an adhesive or coating depends largely on the strength of the bond formed between the binder and the substrate. This bond may be chemical in nature, but more commonly it is a physical attachment. The
conformations taken by the large, polymeric binder molecules, both at the surface and in the bulk of the coating, often govern the effectiveness of the bond. Since NMR can be profitably used to study molecular dynamics, such studies can reveal important information about the physical nature of the adhesion between coating and substrate.

2.1 Brief Overview

There are many publications describing the basic features of NMR\textsuperscript{(3,4,11-14)} in addition to some that specifically cover its practical applications to polymer systems\textsuperscript{(9,10)}.

As with many other analytical techniques, proper sample preparation is a crucial first step in the successful acquisition of an NMR spectrum. For solution experiments, obtaining a homogeneous sample is critical; this process can take up to several hours for polymers, which often dissolve poorly and/or slowly. Gentle heating of the sample (below the solvent’s boiling point, obviously) often hastens this step. Deuterated solvents are normally used to prepare NMR samples; the \(^1\)H signal is then monitored to stabilize the instrument’s magnetic field and to optimize its homogeneity. Labeled analogs of many common solvents are available from a variety of sources. Samples for solid-state NMR analysis are, of course, not dissolved but must often be processed into a fine powder so that they can be stably spun at high speeds (several kilohertz). In all cases (solutions and solids), the inclusion of metal as an additive or substrate may adversely affect the results. Brown-colored materials, which usually contain iron oxide as a pigment, are particularly notorious in this regard.

As mentioned briefly above, NMRs arise from the altered behavior of certain atomic nuclei in the presence of a magnetic field. Any nuclide with nonzero nuclear spin, \(I\), exhibits this interaction. While many common and chemically significant nuclides, such as \(^{13}\)C or \(^{16}\)O, have no nuclear spin, most elements possess at least one isotope that is NMR-active; the ease with which a signal can be observed and the amount of chemical detail that is contained in the spectrum vary widely, however. Examples of commonly observed nuclides are listed in Table 2. Many of the NMR-observable isotopes are naturally present at only low abundances, although in favorable cases, artificial enrichment can be employed to make the signals more easily detected. Furthermore, nuclides with \(I > \frac{1}{2}\) also have quadrupole moments, which tend to broaden the resonances.

The NMR experiment is accomplished by a series of radiofrequency pulses that serve as probes of precessional frequencies of the constituent nuclei. The parameters (e.g. number, length, phase, and spacing) of this pulse sequence determine exactly what data are recorded and whether the end results are quantitative. Different chemical species of a particular nuclide (such as \(^1\)H, \(^2\)H, \(^{13}\)C, or \(^{29}\)Si) resonate in a narrow range around a specific frequency called the Larmor frequency. In a 9.4 tesla (T; 9.4 \(\times\) 10\textsuperscript{4} Gauss) magnet, for example, \(^1\)H nuclides resonate at 400 MHz, \(^{13}\)C nuclides at 100 MHz, and \(^{29}\)Si nuclides at 79 MHz. The chemically induced differences, chemical shifts, \(\delta\), are only a few hertz removed from the precessional frequency; consequently, the chemical shift is usually expressed as the ratio of the frequency shift to the Larmor frequency (Hz/MHz) and cited in parts per million (ppm). Even though different nuclides may exhibit widely separated resonant frequencies, there are interactions, or couplings, among them; these interactions can provide additional information, although they generally also complicate the

\textsuperscript{a} In a 9.4 T magnetic field.
spectrum. For example, under certain experimental conditions, a $^{13}$C signal will split into several $(n + 1$, where $n$ is the number of directly bonded $^1$H's) lines of differing intensities, separated by a coupling constant, $J$. At times, even longer-range interactions can be observed. While such $^{13}$C–$^1$H coupling can provide useful information (identifying CH3, CH2, etc.), it also complicates the spectrum by producing many, often overlapping, lines. It can be easily removed or reduced, however, by a technique called heteronuclear scalar, or $J$, decoupling. Homonuclear couplings (such as $^{15}$C–$^{13}$C or $^1$H–$^1$H) also exist, but their importance depends on the abundance of the NMR-active isotope. Juxtapositions of $^{13}$C–$^{13}$C, for instance, are rare because of the relative paucity of $^{13}$C compared with $^{12}$C in unenriched materials. By comparison, since $^1$H's are essentially 100% abundant, $^1$H–$^1$H couplings are intense and can dominate the spectrum; if necessary, they can be removed or reduced by homonuclear decoupling techniques.

During the course of an NMR experiment, the pulse sequence is repeated many times; the pause between cycles is called the relaxation delay. If the relative peak areas in the final spectrum are required to be quantitative, the relaxation delay must be set long enough to allow the system to return to equilibrium between cycles; this time depends on the chemical identity of the nucleus and on the system’s dynamic behavior (typical lengths are a few seconds to several minutes). If this time is so long that the duration of the experiment will be too great, then the system's dynamic behavior (typical lengths are a few seconds to several minutes). If this time is so long that the duration of the experiment will be too great, then the system’s dynamic behavior (typical lengths are a few seconds to several minutes).

A consequence of the decoupling process, called the nuclear Overhauser enhancement (NOE), can also result in further peak-intensity distortions. While this side effect generally increases the signal-to-noise ratio (normally a benefit), it can affect peaks disproportionately. For quantitative analyses, the NOE is usually removed by gated decoupling, in which the decoupling field is turned off for part of the experiment. Some nuclei, such as $^{29}$Si and $^{15}$N, exhibit a negative NOE, which can actually decrease the signal intensity; in studies involving these nuclei, it is critical to employ gated decoupling.

Over the course of an NMR experiment, the pulse sequence is repeated many times in order to build up a sufficiently large signal to distinguish the details of interest. The signal-to-noise ratio increases as the square root of the number of scans; consequently the duration of an acquisition must be quadrupled in order to double the ratio. For weak signals, this can make for very long experiments (up to several days). Other parameters, such as the length and phase of the radiofrequency pulses are also important in certain NMR experiments; information on these experimental protocols can be found in many references.$^{11–8,11–15}$

While NMR spectra of solids are acquired in a superficially similar manner, the intrinsic differences between solids and liquids necessitate some changes in sample handling, instrumentation, and experimental approach. Molecular motions in solids tend to be anisotropic and slow (on the timescale of a typical experiment) and internuclear interactions are not motionally averaged, as they are in liquids. As a consequence, special techniques must be applied if spectra with relatively narrow, symmetric resonances are desired. For example, in order to obtain a high-resolution $^{13}$C spectrum of a solid, samples are commonly packed into small cylindrical sample holders called rotors, which are then spun rapidly (several kilohertz) about an axis oriented 54.7° to the static magnetic field. This magic-angle spinning reduces anisotropies of chemical shift that result from the lack of rapid molecular tumbling. Decoupling of $^{13}$C–$^1$H is applied, although at a much higher power level than for solution-state NMR, in order to overcome through-space dipolar interactions, as well as the much weaker $J$ couplings. For $^{13}$C, the basic data-acquisition pulse sequence is designed to enhance the signal and reduce the relaxation time (which can be quite long because of the restricted molecular motion) via cross-polarization. The details of such experiments are discussed in greater detail elsewhere.$^{15,16}$

The discussion above clearly demonstrates that there are many different types of information obtained from the NMR phenomenon. Spectra in which all the inter- and intranuclear interactions are fully expressed are so full of overlapping information that they may become difficult to interpret with great specificity. In an attempt to reach a compromise between these inherent complexities and the simplicity needed for readily understandable results, clever experiments have been devised that allow for the spectral information to be selectively recovered. For example, rather than showing the multiplicity of a $J$-coupled $^{13}$C resonance by its splitting pattern, this feature can be indicated by the phase of its signal (i.e. whether it is upright or inverted in the final spectrum), by specially crafted pulse sequences such as distortionless enhancement through polarization transfer (DEPT) and insensitive nuclei enhanced by polarization transfer (INEPT).$^{17}$ Even more complex experimental protocols produce spectra in which the interactions are shown along more than the normal two (frequency–intensity) axes. Examples will be discussed in the following sections.

### 2.2 Identification of Materials

The $^{13}$C spectrum shown in Figure 1 is a typical representation of a one-dimensional spectrum of a polymer...
solution. While it is the particular set of resonance positions and relative intensities that ultimately reveals the material’s identity, generalizations about chemical functionality can be made quickly because the correlations between structures and shifts are well established for most NMR-active nuclei. For example, carbonyl carbons resonate over a fairly narrow range, as do aromatic or alkenic carbons, carbons bonded to nitrogen or oxygen, and so on. For aliphatic structures, it is known that methyl groups tend to appear at lower chemical shift values than do methylene groups, which are at lower values than methines, which resonate, in turn, at lower shifts than quaternaries. Figure 2 shows these correlations for $^{13}$C, $^1$H, $^{29}$Si, and $^{19}$F, the nuclei most commonly of interest for coatings and adhesives. Material identification can be done through deduction from chemical-shift correlations by comparison with published spectra or model compounds or (most likely) through a combination of approaches.

While NMR is undoubtedly useful for basic materials identification, it also serves as one of the most powerful structural characterization techniques, which is able to distinguish subtle molecular details. Stereochemistry, for example, is an important feature of many polymers. Materials made from monomers such as vinyl halides, acrylate esters, or 1-alkenes higher than C$_2$ exhibit tacticity, which arises from pendant-group stereo-inequivalence. In isotactic materials, all of the side groups (X) are on one “side” of the backbone chain [as shown in (36)] while in atactic polymers (37), they are randomly distributed. Syndiotactic chains have alternating placement of the X group. This feature, which can significantly affect bulk properties, is clearly reflected in the NMR spectrum as a pattern of resonances that can be assigned to pairs of stereosequences. In the spectrum of poly(vinyl chloride) for example, [(11); Figure 3], the resonances can be designated as $mm$ [(38): for two sequential meso placements], as $rr$ [(39): for two racemic placements] or as $mr$ [(40): for meso-racemic placement]. A simple comparison of
quantitative peak areas in a spectrum reveals the relative amounts of \( mm, rr, \) and \( nr \). Furthermore, some polymers, such as poly(vinyl fluoride) (10) exhibit regiosequences that can be ‘head to tail’ (41) or ‘head to head’ (42). These are also analyzable from the NMR spectrum, as shown in Figure 4.

The primary use of NMR in chemical analysis is as an identification tool based on the great sensitivity of chemical shift to the details of chemical structure, as seen in the examples above. The technique’s utility can be further enhanced, in many cases, by the observation of more than one nuclide. For example, the \( ^{29}\text{Si} \) spectra of polysiloxanes indicate the material’s molecular weight more unambiguously than the spectra of either \( ^{13}\text{C} \) or \( ^{1}\text{H} \). Furthermore, since the \( ^{29}\text{Si} \) experiment only reflects species that contain that nuclide, components that do not contain silicon do not interfere. Other nuclides, listed in Table 2, are also useful in studying coatings, although the ease with which they can be observed varies; in general, higher resonant frequencies and natural abundances make it simpler to acquire signals of sufficient intensity. Unfortunately, some nuclides that would be expected to be informative, such as \( ^{17}\text{O} \), are generally not studied because of the difficulties of signal detection in an unenriched sample. Other nuclides, such as the metals, tend to give broad peaks, which can obscure chemical details.

Coatings and adhesives are generally complex formulations, and the presence of ingredients other than the binder can complicate the spectrum. For example, water does not interfere in a \( ^{13}\text{C} \) spectrum, but an organic solvent, such as a ketone, does; by comparison, water would contribute a large signal to the \( ^{1}\text{H} \) spectrum. Solid additives, such as inorganic pigments, may degrade the spectral quality because they disturb the magnetic-field homogeneity. Brown or orange pigments are particularly troublesome because they often contain ferromagnetic iron species, which can make the spectrum nearly uninterpretable as a consequence of severe line broadening.

2.3 Curing/Drying Reactions and Kinetics

Characterization of the mechanism and kinetics of curing and/or drying reactions first requires an understanding of correlation of chemical shifts with structure, as described above. If spectra are recorded as a function of time, changes in the positions and/or intensities of resonances reveal the details of the reactions taking place. For example, the evaporation of water from a latex material can be readily followed by the loss of the $^1$H signal due to water. Since this process is fairly slow (hours to days), the length of the actual NMR measurement (minutes to hours) is not a significant detriment, as it might be for faster reactions.

The curing of commercial coating materials typically involves processes more complex than simple evaporation. In the urea-formaldehyde resin system, for example, there are many possible reaction sites, leading to a complex chemistry of reaction products (Scheme 1). Complementary studies ($^{13}$C and natural abundance $^{15}$N) reveal many details of the curing reactions, as each of these structures exhibits unique resonances for one or both nuclei. Solid-state NMR techniques can be used to distinguish them and characterize the final material.

2.4 Adsorption/Surface Phenomena

The efficacy of a coating or adhesive relies heavily on its ability to bond with the substrate, and on the sensitivity of this bond to environmental conditions. Any experimental tool that can elucidate the nature of this chemical or (more commonly) physical phenomenon is valuable. NMR, particularly the solid-state experimental variants, fills this need, as illustrated by a recent study of the adsorption of poly(methyl acrylate)-d$_3$ (19) onto silica. Incorporation of a deuterium label into the polymer and subsequent observation of the $^2$H resonance clearly revealed the presence of at least two dynamically distinct components. The polymer chains at the silica interface were motionally constrained, while those on the surface of the coating exhibited considerably more freedom, as illustrated in Figure 5. The temperature-dependent behavior of this system was also studied, and since the correlation between molecular dynamics and $^1$H lineshapes is well established, a detailed model of polymer chain motion occurring in this model coating could be developed.

The ability of NMR to distinguish chemical entities within a polymer can provide insight into the adsorption of more complex systems. In particular, in the blocky poly(styrene-co-4-vinylpyridine) (43) [26222-40-2] the vinylpyridine moiety was found to be preferentially adsorbed onto silica. (Reprinted with permission from Lin and Blum, Copyright (1997) American Chemical Society.)
NUCLEAR MAGNETIC RESONANCE OF COATING AND ADHESIVE SYSTEMS

absorbed onto silica [112945-52-5], titanium dioxide [1317-80-2], and calcium carbonate [471-34-1]. In this case, solid-state NMR was not used; instead, the disappearance of the copolymer from the supernatant solution was tracked.

3 SPECTRAL FEATURES OF COMMON COATING AND ADHESIVE MATERIALS

It should be obvious from the foregoing discussions that a basic understanding of the chemical attribution of each observed resonance in an NMR spectrum is critical to the technique’s effective use. The following sections, therefore, briefly review these correlations for the types of material commonly found in coating and adhesive formulations and show some typical spectra. In all cases, the $^{13}$C and $^1$H chemical shifts are included, but other relevant nuclides are discussed where appropriate.

3.1 Vinyl Polymers

Vinyl polymers commonly used as coatings or adhesives include ethylene copolymers such as poly(ethylene-co-ethyl acrylate) (2), polypropylene (4), isobutylene homopolymer (5) and copolymers, poly(styrene-co-butadiene) (7), vinyl acetate homopolymer (8) and copolymers, poly(vinyl alcohol) (9), poly(vinyl fluoride) (10), vinyl chloride homopolymers (11) and copolymers, vinylidene chloride homopolymer (13) and copolymers and poly(methyl vinyl ether) (14). All have essentially linear, hydrocarbon backbones; the pendant groups vary (see Table 1 for structures). Because the chemical functionalities of the side groups are different (e.g. alkyl chain, halide, ether, or ester), it is difficult to predict the spectrum a priori; identification is best made by comparison with published data for known materials or model compounds.18–20 Backbone carbons not attached to anything other than hydrogen or another carbon, and any carbon-only pendant groups, resonate between 10 and 60 ppm, depending on the exact type of carbon (methyl, methylene, etc.) and on the exact structure surrounding it. Approximate peak positions for the carbons in other groups (such as esters) can be deduced from Figure 2(a).

Many of these spectra exhibit the subtle features associated with tacticity (section 2.2); this effect is particularly significant for the backbone and for any carbons immediately attached to it, as illustrated in the $^{13}$C-NMR spectrum of atactic polypropylene (Figure 6). In solid-state spectra, the tacticity features are usually obscured by residual broadening.

In some cases, $^1$H-NMR can provide useful information about coating and adhesive systems, but it is not usually the nucleus of choice for study of these materials because polymers tend to give broad resonances that can be difficult to resolve. $^{19}$F spectra of fluoropolymers can be used to characterize both tacticity and regioselectivity; two-dimensional NMR has been particularly useful for studying these structural features.25,26 In general, neither $^{35}$Cl nor $^{37}$Cl provides enough chemical detail to be useful for the investigation of vinyl chloride or vinylidene chloride polymers.

3.2 Epoxies and Phenolics

Epoxies generally have a phenolic structure, but not all phenolic resins (15–17) encountered in coatings applications are epoxies. As illustrated in Figure 7, which shows the $^{13}$C spectrum of poly(bisphenol A-co-epichlorohydrin) (15), peaks indicating aliphatic ether linkages appear at 60–100 ppm for $^{13}$C (4–6 ppm for $^1$H); the phenolic moiety gives rise to $^{13}$C resonances in the aromatic region, ranging from 110 to 150 ppm. In particular, the aromatic carbon ortho to the oxygen resonates at approximately 115 ppm, in an uncommon chemical shift range; the appearance of a peak at this point
strongly suggests the presence of a phenolic functionality. Epoxy materials are generally formed in situ from two components that react to create the final product. Solution NMR can easily describe the structure of the starting materials, and the technique can also be used to follow the polymerization reaction if spectra are acquired as a function of curing time.

The other types of phenolic resin used in coatings are the resoles (16) and the novolacs (17), which are phenol-formaldehyde products. The use of a base as the catalyst for a resole, and an acid for a novolac, ultimately leads to slightly different structures. The prepolymers can be studied by solution NMR (13C, 1H, and 15N), but the final cured coatings are insoluble owing to their highly cross-linked nature. Solid-state techniques can elucidate these structures.27,28

3.3 Cellulosics

Cellulosics are basically polyethers, comprising linked six-membered saccharide rings (18). The hydroxyl groups are usually derivatized, most commonly as ethers and esters. The resonances of these materials are often rather broad because of their limited solubility. The 13C ring resonances appear between 70 and 105 ppm, and the carbons in the pendant groups appear where appropriate for the specific type. An example of this, cellulose triacetate [18], where R is acetate [9012-09-3], is shown in Figure 8; this compound exhibits the carbonyl and methyl signals typical of acetate groups, in addition to the saccharide peaks. For the substituted cellulosics, incomplete derivatization may introduce additional resonances; some of the small peaks in Figure 8 result from the presence of mono- and diacetate forms. Starch-based adhesives exhibit spectra very similar to those of the cellulosics.

3.4 Acrylates, Polyesters, and Alkyds

While acrylic polymers and aliphatic polyesters have different backbone structures in Table 1, their spectra often appear similar because ester groups are present in both (see Figure 1 for example). Such carbonyl carbons resonate between 165 and 180 ppm, while C–O is observed in the 50–80 ppm range (for acrylates and aliphatic polyesters). Acrylates (along with the related methacrylates and cyanoacrylates) are used as bases for many latex paints and adhesives. Such water-based systems also contain an elastomer, most commonly cis-polyisoprene (28) or natural rubber (Figure 9). The cyanoacrylates, which are used in “super glues”, are important components of many adhesives; the α-C≡N peak (27) appears around 120 ppm. 1H spectra of these materials can be quite informative, as the position of the pendant OCH may change significantly with the identity of this group.16

Polyesters used as coatings are typically based on terephthalic acid and give 13C spectra similar to that of poly(ethylene terephthalate) (29); Figure 10. It should be noted that many polyurethanes (section 3.6) contain ester segments; these should not be confused with polyester resins. Alkyd resins are based on polyesters made with unsaturated diacids such as maleic [110-16-7] and fumaric [110-17-8] acids, or with unsaturated diols like allyl alcohol [107-18-6]. During curing, a network forms through the double bonds; this can be followed...

from the decrease in signal intensity in the $^{13}$C chemical shift region 110–140 ppm.

3.5 Oil-based Coatings

Oil paints are based on unsaturated plant oils, such as linseed oil [8001-26-1]; the $^{13}$C spectrum of an epoxidized form of this material is shown in Figure 11. These oils are usually glycerol esters of various unsaturated fatty acids, such as oleic, linoleic, and linolenic acids. The $^{13}$C spectrum, therefore, exhibits a complex pattern of resonances, with carbonyls at 170–180 ppm, alkenic carbons at 110–140 ppm, C–O at 50–80 ppm, and aliphatic groups at 10–60 ppm. As the paint cures, the double bonds open, leading to network formation and a concurrent decrease in intensity in the 110–140 ppm region.

3.6 Polyamides, Amino Resins, and Polyurethanes

The nitrogen-containing materials fall into a number of different chemical classes. Amide linkages are found in polyamides (nylons), some amino resins, and the polyurethanes. The $^{13}$C spectra of these materials may appear, at first inspection, similar to those of the polystyrenes, but there is no C–O resonance between 50 and 80 ppm. The nylons are linear polymers that are formed by ring-opening polymerization of a lactam or by co-reaction of a dicarboxylic acid and a diamine. The resulting material is designated as “Nylon X” or “Nylon XY”, where X indicates the number of carbons in the lactam or in the diacid, and Y the number in the diamine. It is possible to determine X and Y based on relative peak areas, but the distinction is more readily achieved using melting points. Amino resins are products of the reaction of formaldehyde [50-00-0] with either urea [57-13-6] or melamine [108-78-1]. The system discussed in section 2.3 is an example of a urea-formaldehyde resin (31). Since the resulting structure of this type of polymer is, essentially, a highly cross-linked polyamide, its spectrum is similar to that of a nylon. Melamine-formaldehyde resins [68002-25-5] contain triazine rings, which give rise
to $^{13}$C resonances in the aromatic region between 110 and 150 ppm. Polyurethanes also contain amide structures in the backbone, but these segmented materials also include long polyether and/or polyester blocks. In many cases, these will be the dominant resonances in the spectrum, as shown in Figure 12. In addition to $^{13}$C NMR, $^{15}$N experiments (either with an enriched sample or in natural abundance) can be used specifically to study reaction sites, without possibly complicating signals from the carbon-containing parts of the molecule.

### 3.7 Silicones and Silicates

Silicon-containing polymers such as the silicones and silicates [for example, (33) and (34)] are relatively easy to identify by either $^{13}$C or $^1$H NMR. The presence of the silicon atom dramatically affects the shift of any carbon (or of any hydrogen bonded to a carbon) directly attached to it, causing it to resonate near 0 ppm. In fact, the common chemical shift reference, tetramethylsilane [75-76-3] is defined as 0 ppm for both $^{13}$C and $^1$H. Furthermore, $^{29}$Si NMR is a particularly useful tool for the study of these materials, as it provides much structural information. There is, for example, a significant difference in chemical shift, depending on whether the silicon is bonded to one, two, three, or four oxygens (types M, D, T and Q, respectively; see Figure 2c). The most common silicon-containing coating materials are type D, such as polydimethylsiloxane (33). In some cases, even more details are available; the spectrum shown in Figure 13 illustrates this point for poly(ethyl silicate) (34). The four groups of resonances clearly indicate silicon atoms that are attached (through an oxygen bridge, Q type) to one, two, three, or four other silicon atoms [(44), (45), (46), and (47), respectively]. The relative intensities of each resonance can be used to determine the amount of each structure. The broad peak that underlies the narrow resonances arises from silicon in the glass tube that contains the sample.

NUCLEAR MAGNETIC RESONANCE OF COATING AND ADHESIVE SYSTEMS

3.8 Metal Oxides

Many metals are provided with protective coatings by allowing the surface to oxidize slightly. This thin coating can be difficult to observe directly by NMR for several reasons. First, the amount is quite small. Second, the metal substrate may interfere with signal acquisition by creating radiofrequency inhomogeneities; lastly, the particular nucleus may not be appropriate for NMR analysis. However, in some cases, a great deal of information can be obtained from model metal oxide systems. One such example is the investigation of aluminum oxide [1344-28-1] by $^{27}$Al-NMR. The invisibility of some of the surface aluminum atoms suggests that they are different in nature from the bulk. Low-temperature studies indicated that this difference is a consequence of greater molecular motion at the surface.

3.9 Additives and Pigments

Coatings and adhesives are complex formulations, often containing many colorants and other additives. NMR is not a particularly useful technique for the study of pigment species per se, since many are simple inorganic oxides or salts. For example, the most common white colorant is titanium dioxide, and neither titanium nor oxygen is a very facile nucleus for NMR analysis. As discussed previously, brown or orange iron-based colors can severely degrade the quality of the observed signal since their presence induces magnetic-field inhomogeneities. Organic colorants can, in principle, be observed by NMR, but a mutually suitable solvent for pigment and binder must be found, which may be difficult. However, NMR can be used to study the behavior of other formulation additives, such as the antiplasticizers that modify the physical properties of the base material. Sophisticated multidimensional solid-state techniques ($^2$H, $^{15}$N, and $^{13}$C rotational-echo double resonance) have been employed to pinpoint the location of such an additive in a cross-linked epoxy resin. Since the experiment involves the measurement of geometry-dependent $^2$H–$^{15}$N and $^{15}$N–$^{13}$C couplings, isotopically enriched samples must be prepared. These measurements revealed the average distance of the additive’s carbonyl from the amine nitrogen and the quaternary carbon of the epoxy resin and indicated that the additive has no preference for either the free or the cross-linked amine sites.

4 CONCLUSION

Because of the great wealth of molecular detail that can be extracted from NMR spectroscopy, the technique finds applications even to systems as complex as coatings and adhesives. It is particularly useful for studying model systems examining the mechanisms and kinetics of the drying or curing reaction and to achieve insight into the physical basis of adhesion.

REFERENCES

Rheology by definition is the study of the deformation and flow behavior of materials. An operational definition would be “the study of the response of certain materials to the stresses imposed on them”. Rheology seeks to understand the relationship between applied force, or stress, and the resulting deformation, particularly for materials showing nonsimple responses. Such a relationship expressed mathematically is termed a constitutive equation. Perhaps the most familiar such equation is Hooke’s law for elastic solids, which states the linear relationship between the stress $\sigma$ and the deformation or strain $\gamma$ [Equation 1]:

$$\sigma = G\gamma$$

(1)

where the modulus $G$ is the constant of proportionality. However, rheology is primarily concerned not with the solid state but with the study of fluid behavior, and the simplest constitutive relation for a liquid is Newton’s law [Equation 2]:

$$\sigma = \eta\dot{\gamma}$$

(2)

where the coefficient of viscosity or, more commonly, the viscosity $\eta$ expresses the proportionality between stress and, now, not strain but the strain rate, $\dot{\gamma}$.

For the ideal, simple materials described above, $G$ and $\eta$ are called material constants because they are dependent only on the thermodynamic variables of temperature, pressure, and concentration, similar to a material property such as the density. However, rheology is not concerned with either Hookean solids or Newtonian liquids. It is rather concerned with materials whose constitutive relationships involve complex behavior. For such materials, $G$ and $\eta$ are no longer material constants but material functions. Their values will now depend on variables such as the magnitude of applied stress, strain, strain rate, and even the deformation history. In fact, for rheologically interesting materials, the behavior is somewhere between that of a Newtonian liquid and an elastic solid. Such materials are termed non-Newtonian, and may display time-dependent, plastic and viscoelastic behaviors.

Paints and industrial coatings, creams and lotions, inks, adhesives, ceramic slips, solder pastes, foods, medicines, etc. are representative of the range of materials whose commercial viability depends on having the correct rheological properties. The required rheological properties must be defined with reference to the specific process at hand. This article introduces the science of rheology, with description of basic terms, models, and methods used. The mechanisms responsible for complex rheological behavior and the use of rheological measurements to understand and control the flow of materials are described. The emphasis is on coatings and coatings processes as points of reference, but the principles discussed apply to a wide range of materials and industrial products.

---

**1 INTRODUCTION**

This article presents a brief review of principles and methods of rheological analysis, directed toward the coatings industry. The title of the article mentions coatings, but this could also include adhesives, inks, and sealants. These products share a common task: they must be applied to a substrate and function as a thin film. This process of application and film formation obviously requires not only a large total deformation, but also a high degree of control of flow, to achieve success. Flow cannot be controlled unless it can be properly measured. A persistent fault of industrial viscosity tests is that the methods do not closely relate to actual coating processes. This deprives the test of relevance to product performance. Moreover, the majority of commercial fluid products are non-Newtonian, and the rugged but simple viscometers commonly used in the industrial laboratory are generally not well suited for the characterization of non-Newtonian fluids. The objective for the applied rheologist, therefore, is to develop methods of rheological characterization that:

1. yield accurate data for complex fluids;
2. are related specifically to the critical processes that paints must undergo.

To meet the latter goal requires characterization methods that cover a wide range of stresses and timescales.

Even though all other properties be acceptable, a coating will usually not meet with success if the rheology is not. Experienced formulators say that more than half the cost of new product development is consumed in getting the rheology right. Furthermore, apparently minor changes in a raw material or process can cause significant and unexpected variability in product rheology, which naturally requires urgent solution. For all these reasons, rheological analysis is a vital and cost-effective tool for the coatings industry.

**2 BASIC DEFINITIONS**

**2.1 Rheology**

The term rheology derives from the Greek ῥήειν, “to flow”. Rheology is defined classically as “the study of the deformation and flow of matter”, and operationally as “the study of the response of certain materials to stress”. In order to quantify the deformation and flow behavior of materials, three basic terms must be defined. The first two of these relate to the measurement of deformation (strain and strain rate) and the third to the measurement of the force necessary to deform the material (stress).

**2.2 Deformation (Strain)**

A deformation (or strain) is a change in shape and/or volume of a material in response to an applied stress. There are two main types of deformation: reversible (elastic, rubber-band-like), and irreversible (inelastic or viscous). Irreversible deformation is the definition of flow. Rheologically interesting materials display a third type, in which either or both a viscous and an elastic response to stress can be seen, depending on the rate or the duration of applied stress.

During the processing and end-use of a coating the deformation history can be complex. The most important types of deformation it will experience are simple shear and extension. (Extensional rheometry will be excluded from this presentation, because (a) a very limited number of studies on paint extensional rheology exist, and (b) in the author’s opinion, there are no commercial instruments well suited to extensional characterization of paints.) For purposes of definition, the discussion is limited to simple shear. Simple shear deformation is exactly analogous to the spreading of a deck of playing cards, each card representing a thin volume element displaced relative to its nearest neighbor (Figure 1). If a force \( F \) is applied to the uppermost volume element (thickness \( dy \)), the material will deform by the displacement \( dx \) of adjacent volume elements. The total thickness is \( \Delta y \), and the total displacement is \( \Delta x \). The shear strain \( \gamma \) is the ratio of the net displacement \( \Delta x \) to the distance between the confining surfaces \( \Delta y \) [Equation 3]:

\[
\gamma = \frac{\Delta x}{\Delta y}
\]

**2.3 Strain Rate**

Unlike solids, such as a rubber band, liquids cannot support a constant deformation or strain. In order to measure the viscosity or resistance to flow of a fluid we therefore do not measure the deformation, but instead
the rate of deformation (strain rate). The strain rate is the change in strain per unit time or the time derivative of the strain, symbolized \( \dot{\gamma} \) (where the dot signifies “time derivative of”). Therefore, Equation (4) holds:

\[
\dot{\gamma} = \frac{dy}{dt} = \frac{d(dx/dy)}{dt} = \frac{d(dx/dt)}{dy} = \frac{dy}{dy}
\]

If the deformation is simple shear, the strain rate is called the shear rate. The dimensionality of \( \dot{\gamma} \) is LT\(^{-1}\) (e.g. cm s\(^{-1}\) cm\(^{-3}\)). Unit cancellation leaves reciprocal time (s\(^{-1}\)) as the unit of shear rate. It is conceptually helpful to remember that, as shown by Equation (4), the shear rate is actually a velocity gradient, dv/dy (change in velocity per unit gap between shearing surfaces).

### 2.4 Stress

A force applied to a material creates a state of stress within the material. Stress can be expressed in units of force per unit area (e.g. dyne cm\(^{-2}\)) or, equivalently, energy per unit volume (e.g. erg cm\(^{-3}\)). In terms of Figure 1, the shear stress \( \sigma \) is the force \( F \) necessary to maintain steady shearing motion against the resistance of the fluid, divided by the area of the shear face, \( A \) [Equation 5]:

\[
\sigma = \frac{F}{A}
\]

The stress is determined not only by the magnitude of the applied force, but also by the area over which it is applied. Stress can therefore be thought of as a kind of force density, or the “concentratedness” of the force. Consider the analogy of a weight applied to a mattress. The depth to which the weight sinks into the mattress depends on the area over which the force is applied. The smaller the area of contact of the weight with the mattress, the higher the stress, and the greater the resulting strain, or the deeper the weight sinks.

### 2.5 Viscosity

The measure of the resistance to flow of a fluid is the viscosity. The resistance to flow is caused by friction between the flow units of the fluid (e.g. molecules), or may also be due in part to forces of attraction between the flow units. Thus, a highly viscous fluid (one reluctant to flow) may be so because of high molecular weight (as in motor oil) or may be of relatively low molecular weight, but have strong intermolecular interactions (e.g. hydrogen bonds, as between sugar molecules in honey).

The interaction of molecules in flow dissipates energy, chiefly as frictional heat. Flow, therefore, is a process that costs energy, of which the viscosity is a measure. For the case of shear deformation, the viscosity \( \eta \) is calculated as the ratio of shear stress to shear rate. As stated above, the shear stress represents the energy input per unit volume to achieve flow. The viscosity, therefore, is the energy dissipated per unit volume per unit velocity gradient [Equation 6]:

\[
\eta = \frac{\sigma}{\dot{\gamma}}
\]

Note that the rate of viscous energy dissipation (the power per unit volume) is the viscosity times the square of the shear rate, \( \dot{\gamma}^2 \). The latter is the cause of viscous heating in fluids under shear.

### 2.6 Modulus

Materials comply with an applied stress by deforming, or undergoing strain. For ideal Hookean materials, the strain will be proportional to the applied stress. The modulus is the proportionality constant between the stress and strain. For example,

\[
G = \frac{\sigma}{\dot{\gamma}}
\]

where in Equation (7) the shear modulus \( G \) is equal to the ratio of the shear stress and shear strain. Most polymeric materials and coatings systems in the solid state are non-Hookean, i.e. the modulus is not a material constant, but will depend on both rate and extent of deformation.

### 2.7 Units

Until recently, the most common system of units for rheological terms was the cgs (centimeter–gram–second) or “small metric” system. However, international convention now specifies Système International (SI) units.

as the standard. The SI system is based on the large metric, or mks (meter–kilogram–second) units, with some additional named units. The units associated with the above variables according to the various systems are given in Table 1.

3 GENERAL CLASSES OF FLUID BEHAVIOR

3.1 Newtonian Fluids

It was postulated by Newton that the force resisting flow of a liquid is proportional to the rate at which it is caused to flow. Restated in terms of the above-defined quantities, the stress is proportional to the strain rate and the constant of proportionality is $\eta$, the coefficient of viscosity or, simply, the viscosity:

$$\sigma = \eta \dot{\gamma}$$  \hspace{1cm} (8)

Equation (8) is the simplest example of a constitutive relationship, a model relating an applied stress and the response of a material. Fluids that obey Equation (8) over a range of shear rate are said to be Newtonian over that range. The viscosity of a Newtonian fluid is a material constant and depends only on the thermodynamic variables of temperature, pressure, and concentration. If the viscosity of such a material is measured at any shear rate or shear stress, the viscosity under all conditions of deformation is known (excluding turbulent flow).

3.2 Non-Newtonian Fluids

Commercial fluid products comprise a variety of materials, with a wide range of consistencies. In general, polymer solutions, emulsions, colloidal dispersions, and other suspensions of particulate solids will be non-Newtonian. For non-Newtonian materials, the viscosity is no longer a material constant, but is now a material function – in this case a function of the shear rate (or shear stress). For non-Newtonian fluids, a viscosity measured at a single shear rate is not an adequate representation of the rheology of the system.

4 CLASSES OF NON-NEWTONIAN BEHAVIOR

4.1 Shear-dependent Viscosity

Materials for which the viscosity falls with increasing shear rate are said to be shear thinning. (Any descriptions of behavior stated in terms of shear rate-dependence may equally well be stated in terms of shear stress dependence.) Simple shear thinning without either time dependence or a yield stress is termed pseudo-plasticity. Viscosity rising with increasing rate of shear is called shear thickening. The term “dilatancy” is often applied to shear-thickening behavior, although this refers strictly to shear thickening accompanied by a volume increase, as the term implies. Figure 2 shows curves illustrating viscosity–shear rate relationships for Newtonian and non-Newtonian fluids.

Equation (8) describes simple fluid or Newtonian behavior, for which the viscosity $\eta$ is a material constant, independent of shear rate (contour N, Figure 2). As flow behavior becomes more complicated, a more complex expression is needed to model it. First, to the Newtonian model we will add a yield stress (section 4.5), giving the Bingham equation:

$$\sigma = \sigma_0 + \eta_p \dot{\gamma}$$  \hspace{1cm} (9)

Equation (9) says that, when the applied stress $\sigma$ is greater than the yield stress $\sigma_0$, the difference $\sigma - \sigma_0$ is directly proportional to shear rate. Note that the Bingham model and others containing a yield stress term describe flow behavior only when $\sigma > \sigma_0$. That is, if $\sigma \leq \sigma_0$, $\dot{\gamma} = 0$ (i.e. $\eta = \infty$), and there is no flow. Contrary to what is often stated, this does not correspond to Newtonian behavior above the yield stress. As illustrated in Figure 2 the Bingham model (curve B) displays shear-thinning behavior (when $\sigma > \sigma_0$), but the viscosity approaches the plastic viscosity $\eta_p$ as a limit at higher shear rate. Casson(2) derived an equation similar to Bingham’s for the flow of a dispersion, except all terms are present as the square
models (see below). The term does not represent paint flow as well as certain other systems, particularly as modified by Asbeck (curve HB, Figure 2). Lapasin and Torriano which describes power law behavior above the yield point gives the Herschel–Bulkley relationship [Equation 14]:

\[ \eta^{1/2} - \eta_\infty^{1/2} = \frac{\sigma_0}{\gamma} \gamma^{1/2} \]  

(10)

Casson’s equation is reputed to fit a variety of paint systems, particularly as modified by Asbeck

\[ \eta^{1/2} - \eta_\infty^{1/2} = \frac{\sigma_0}{\gamma} \gamma^{1/2} \]  

(11)

In fact, the author’s experience is that the Casson model does not represent paint flow as well as certain other models (see below). The term \( \eta_\infty \) in Equations (10) and (11), sometimes called the Casson viscosity, is not literally an “infinite-shear viscosity” but is a limiting value that is approached at a relatively high shear rate. The analysis of flow data using these models is simply an exercise in curve fitting, and the value obtained for \( \eta_\infty \) can vary depending on the completeness of the dataset used in the analysis. The user should be aware that the parameters resulting from a Casson analysis, as with all such models, are not necessarily true material constants. For example, a finite yield stress will generally be obtained whether or not the material really possesses yield behavior.

Next, we will let the exponent of the shear rate in the Newtonian law to be other than unity. The shear stress is now proportional to the shear rate to the power \( n \):

\[ \sigma = K \gamma^n \]  

(12)

Equation (12) is known as the power law or Ostwald–deWaele model. The constant \( K \), sometimes called the consistency, has replaced the coefficient of viscosity \( \eta \). (In numerical magnitude, though not dimensionally, \( K \) is the viscosity at unit shear rate, \( 1 \, \text{s}^{-1} \).) This is necessary because the exponent \( n \) can be other than unity, in which case \( K \) will not have proper viscosity units associated with it. The power law exponent \( n \) is sometimes called the flow index because a value of \( n < 1 \) corresponds to shear thinning behavior and \( n > 1 \) to shear thickening (Figure 2 curves PL). Dividing Equation (12) through by \( \gamma \) yields the viscosity power law [Equation 13]:

\[ \eta = K \gamma^{n-1} \]  

(13)

Substituting \( n = 1 \) in Equations (12) and (13), yields back the Newtonian law.

Adding a yield stress term to the power law expression gives the Herschel–Bulkley relationship [Equation 14]:

\[ \sigma - \sigma_0 = K \gamma^n \]  

(14)

which describes power law behavior above the yield point (curves HB, Figure 2). Lapasin and Torriano showed the Herschel–Bulkley model to be superior to a number of others in fitting the flow behavior of a wide variety of coatings materials over a useful range of deformation conditions.

4.1.1 Generalized Equilibrium Flow Curve

The generalized equilibrium flow curve (Figure 3) represents the general features of the shear rate dependence of viscosity for non-Newtonian fluids (after Hoffman, Krieger, and Choi). The condition “equilibrium flow” means that any time-dependent or relaxation effects have been experimentally removed. Figure 3 consists of:

1. a low shear rate Newtonian regime, region I;
2. a shear-thinning regime, the power law regime, region II;
3. a high-shear Newtonian regime, region III;
4. a possible shear-thickening regime, region IV.

The figure is explained in more detail in section 4.2. The chief shortcoming of the power law models is that their range of validity is limited to region II. They cannot account for the upper or lower Newtonian regions, and predict infinite viscosity at zero shear rate and zero viscosity at infinite shear rate, both unrealistic limiting behaviors. However, the power law models (Ostwald–DeWaele, Casson, Herschel–Bulkley) are useful within their limitations, particularly for engineering-type calculations. More elaborate models are required to fit the generalized non-Newtonian curve beyond the power law region. A simple extension of the power law model is to add an upper Newtonian limiting viscosity, \( \eta_\infty \):

\[ \eta = K \gamma^{n-1} + \eta_\infty \]  

(15)

Equation (15) is known as the Sisko model, and includes regions II and III of Figure 3.

Modern rheometers have made the low-shear Newtonian plateau viscosity \( \eta_0 \) more experimentally accessible, and models incorporating region I are quite useful. Perhaps the two most successful of several proposed models encompassing regions I, II, and III inclusively are the

![Figure 3 Generalized non-Newtonian equilibrium flow curve. \( \eta_0 \) = zero-shear viscosity; \( \eta_\infty \) = high-shear limiting viscosity; region I = first Newtonian plateau; region II = power law regime; region III = second Newtonian plateau; region IV = shear-thickening behavior. (Adapted from Choi.)](Image)
Cross and Carreau models. Hieber and Chiang have written a general form of which the Cross and Carreau models are special cases (modified here to include region III; Equation 16):

\[
\eta = \eta_\infty + \frac{\eta_0 - \eta_\infty}{(1 + [\beta \gamma]^g)^{1 - \alpha/a}}
\]

(16)

where \(\eta_0\) is the first (lower) Newtonian plateau viscosity and \(\eta_\infty\) the second (upper) Newtonian viscosity. The constant \(a\) determines the curvature of the transition region between the first Newtonian regime and the power law regime. The value of \(a\) can be a measure of the breadth of the molecular weight distribution of a polymer or the particle-size distribution of a colloidal dispersion. Setting \(a = 1 - n\) in the above expression yields the Cross equation, whereas \(a = 2\) gives the Carreau-B model. The parameter \(n\) has the identical meaning as in the simple power law model [Equations 12 and 13], i.e. it is the slope of the power law region in a log-log plot of shear stress versus shear rate. The constant \(\beta\) has the dimension of time and is a time constant characteristic of the available mechanisms permitting the system to accommodate to a shear field. It may thus be related to the diffusional or rotational relaxation time of the flow units (e.g. colloidal particles or aggregates) or perhaps to the time for rupture of particle flocs or aggregates under shear. The characteristic shear rate of the transition from the initial Newtonian plateau (region I) to the shear-thinning regime (region II) in Figure 3 is determined by the value of \(\beta\) [Equation 17]:

\[
\dot{\gamma}_{tr} = \frac{1}{\beta}
\]

(17)

For colloidal systems, \(\beta\) is the time constant for Brownian diffusion. The Stokes–Einstein equation leads to the value of \(\beta\) for a spherical-particle dispersion [Equation 18]:

\[
\beta = \frac{6\pi \eta R^3}{k_B T}
\]

(18)

where \(\eta\) is the viscosity of the continuous phase, \(R\) is the particle radius, \(k_B\) is the Boltzmann constant, and \(T\) is the absolute temperature. It should be said that Equation (18) is quantitatively correct only for very dilute dispersions. However, this expression is qualitatively useful for rationalizing the behavior of more concentrated dispersions that display Brownian motion. Here, \(\beta\) is the time to diffuse a distance equal to a particle radius.

Shear thinning involves a transition from Brownian to hydrodynamic dominance of the microstructure. (This event corresponds to the point \(c\) in Figure 3.) This transition from Newtonian to shear thinning can be expressed in terms of the Peclet number, \(Pe\), a dimensionless shear rate [Equation 19]:

\[
Pe = \frac{6\pi \eta \gamma R^3}{k_B T}
\]

(19)

The numerator represents the viscous resistance to particle diffusion and the denominator the thermal energy driving Brownian motion, so that the transition from the Brownian to the hydrodynamic regime occurs as \(Pe\) exceeds unity. It is useful, however, to express this transition in dimensional terms, and the dimensional shear rate of transition is \(1/\beta\) [Equation 17].

Equations (17) and (18) suggest ways of controlling the onset of shear thinning for a dispersion. Any change that increases the value of \(\beta\) (such as increasing the effective particle size, the continuous-phase viscosity, or lowering the temperature) will reduce the onset of shear thinning to lower shear rates. Decreasing \(\beta\) extends Newtonian behavior to higher shear rates. Although Equation (18) is strictly valid only for very dilute dispersions, it still provides qualitative guidelines for manipulating the rheology of dispersions. For concentrated dispersions, \(\eta\) can be taken as the viscosity of the dispersion.

A broad particle-size distribution will possess a range of \(\beta\) values, a corresponding range of \(\dot{\gamma}_{tr}\) values, and consequently the transition to shear thinning will be spread out over a wide range of shear rates. Thus, the effect of polydispersity in the flow unit size distribution will be to make more gradual the transition from region I to region II. The mean shear rate of transition corresponds to a mean diffusion relaxation time, whereas the value of \(a\) in Equation (16) will vary according to the distribution of relaxation times. Thus, a colloidal dispersion having a wide particle size distribution will exhibit a broad, gradual transition from region I to region II. A similar effect will be seen in a polymer melt of broad molecular-weight distribution.

### 4.2 Shear-thinning Fluids

Fluids that show decreasing viscosity with increasing shear rate (or shear stress) are often called pseudoplastic, an obsolescent term that implies shear-thinning behavior without yield stress. Currently, the more descriptive (but longer) phrase “time-independent shear thinning” is used to refer to this behavior. Particulate dispersions, polymer colloids, and polymer solutions can display this behavior above a concentration threshold. Pseudoplastic fluids display shear thinning without time dependence, meaning that at a constant shear rate and temperature the viscosity also remains constant. In a ramp experiment (discussed below), the up-ramp and down-ramp curves for such a material will be coincident. This behavior implies that the fluid microstructure is always at equilibrium despite
conditions of changing shear rate. In other words, the microstructure can adjust to a change in shear rate faster than the shear rate is changing. Put another way, the microstructural relaxation time is faster than the time-rate-of-change of the shear rate \( \dot{\gamma} \). Thus, the microstructure effectively equilibrates instantaneously when the shear rate is changed. Therefore, one always measures the equilibrium viscosity for such fluids. Of course, it may be possible to increase the shear rate rapidly enough (as by a shear rate step-jump transient experiment) to observe the microstructural relaxation time for a given system.

4.2.1 Mechanisms of Shear Thinning

Two principal mechanisms for shear thinning in dispersions are:

1. For unstable (flocculating) systems, shear thinning results from the break-up of floc structures, releasing interstitially trapped liquid phase, reducing the effective volume fraction (section 5), hence lowering the viscosity. Once flocs have broken down, shear thinning can proceed further by mechanism (2).

2. For stable (nonflocculating) colloidal systems, shear thinning results from the progressive domination of microstructure-randomizing Brownian motion by hydrodynamic shear forces. This induces ordering of particles in strings (ordered layers of particles in concentrated dispersions), which is a more efficient-flowing microstructure. Hydrodynamic ordering also leads to shear thinning for noncolloidal (non-Brownian) systems.

The following discussion applies to nonflocculating systems and excludes, for the present, the case of flocculated systems, which are addressed in section 4.4.2.

The viscosity is a measure of the energy cost to flow. Therefore, shear thinning implies a change in the microstructure that allows more efficient flow, consequently with less energy dissipation. The mechanism of this involves a shear-induced increase in order, or anisotropy, within the system. Thermal (Brownian) motion tends to keep systems disordered (of random order). Shear forces work against this, tending to impose order. For particulate dispersions, this means that individual particles tend to align with the shear field, in a string-of-pearls fashion (Figure 4). This alignment tends to reduce the degree of frictional interaction between individual particles and the surrounding fluid, making the flow more energy efficient, hence reducing the viscosity. For the case of polymers in solution, polymer random coils tend to stretch in the direction of shear, and become ellipsoidal in shape, with the major axes aligned at a 45\(^\circ\) angle to the flow direction. The result is a steadily decreasing viscosity with increasing shear rate as the degree of order increases. This describes region II in Figure 3. Ultimately, at high shear rates, the maximum amount of shear ordering possible is attained and the viscosity again becomes independent of shear rate (region III in Figure 3, the upper Newtonian plateau \( \eta_1 \)). Particle dynamics simulations confirm this description in a general way, although some of the details are still in question.(18) The general flow curve involves an initial constant-disorder regime (first Newtonian), followed by a disorder to order transition (to the shear-thinning regime), succeeded by a metastable constant-order regime (second Newtonian), and finally an order–disorder transition (shear thickening, regime IV). The onset of shear thickening occurs at progressively lower shear rates as the dispersion concentration increases,(19) with the consequence that one or more of the other regimes are obliterated.

If the dispersion is unstable (flocculated) the viscosity may or may not plateau at low shear. Something similar to the dashed curve in Figure 5 may be seen, the viscosity generally increasing as the shear rate is reduced. Such systems may possess an apparent yield stress (section 4.5). (Section 5 provides an additional discussion of particulate system rheology.)

4.3 Shear-thickening Fluids

It is described above how shear thinning results from a shear-induced increase in the order of a system, which allows the fluid elements to flow with minimum expenditure of energy. Conversely, shear thickening can result from a decrease in the order of a system.
A disordered system flows less efficiently, hence is more viscous. An example of this is the catastrophic increase in viscosity observed by Hoffman in concentrated polyvinylchloride dispersions,\(^5\) postulated to result from the buckling or collapse of ordered, layered arrays of particles.

A common type of shear thickening behavior is dilatancy. The term has sometimes been applied loosely or generically to shear thickening, but dilatant behavior is, strictly, time-independent shear thickening accompanied by an increase in volume of the fluid (implying a decrease in packing efficiency or order). This specific behavior has been referred to as volumetric dilatancy and usually occurs in relatively concentrated disperse systems. In such a dilatant system, the disperse-phase particles are minimally wetted by the liquid continuous phase. At rest, the particles of the disperse phase are in a random close-packed structure, for which the interstitial volume is relatively minimal (Figure 6). If the dispersion in this state is deformed slowly, adequate time exists for the meager liquid phase to flow sufficiently to maintain the dispersed phase in a wetted state, and the system is able to nearly maintain its close-packed structure. Faster deformation causes a liquid-starved condition because the interstitial volume increases when the system is deformed or made to flow (Figure 6). There is no longer enough liquid to lubricate the system. The particles are, therefore, incompletely wetted, may come into direct contact, and further flow would ultimately create microscopic voids leading to fracture of the material. The surface of a dilatant material may appear dry when stressed, due to the withdrawal of surface liquid into the increased interstitial volume. This is seen when walking on wet sand on the beach. The resistance to deformation of the material can increase sharply due to these effects.

The mechanism for shear thickening described above clearly applies to true dilatant behavior, such as can be observed in wet sand and in cornstarch dispersions. For such systems, dilatancy appears when the system at rest is disturbed. Shear thickening occurring in flowing systems with increasing shear rate has been termed rheological dilatancy, and the mechanism here is probably somewhat different. Hoffman’s postulated collapse of particle-layered structures has been challenged by more recent neutron-scattering experiments as well as by computer particle dynamics simulations.\(^{18}\) These studies indicate that shear thickening is the result of particle cluster formation, occurring when hydrodynamic forces overcome stabilizing forces, allowing the formation of shear-induced aggregates.\(^{21}\)

Dilatancy is very sensitive to dilution or warming. Also, introducing polydispersity, adding flocculants (preventing random close packing) or electrolyte (reducing the effective volume fraction of the dispersed phase, section 5) can alleviate undesirable dilatancy. Flow curve measurement provides an excellent means of quantifying the degree of reduction of dilatancy achieved by these measures.

### 4.4 Time-dependent Fluids

For time-dependent fluids, the viscosity depends on the shear history. That is, the viscosity of time-dependent fluids will depend on both shear rate (or shear stress) and time. Time-dependent shear thinning is termed thixotropy, and is common in paints and other flocculated or otherwise structured fluids.\(^{22}\) Its rarer opposite, time-dependent shear thickening, has been called rheopexy, though the preferred term is antithixotropy.

#### 4.4.1 Characteristics of Thixotropy

If a thixotropic fluid is subjected to a constant shear rate and temperature the viscosity will fall, eventually reaching a constant value. If the shear rate is then changed, the viscosity will approach a new equilibrium.

---

*Figure 5* Representation (dotted line) of behavior of flocculated systems at low shear. Instead of a Newtonian plateau, the curve ascends toward possible yield stress (infinite viscosity).

*Figure 6* Dilatant behavior (shear thickening with volume expansion). Random close-packed structure gives way to less-efficient packing, with increase in interstitial volume.
value at a characteristic rate of approach. This behavior is illustrated in Figure 7, showing the way viscosity changes for a time-dependent system when the imposed shear rate (or shear stress) is changed in a series of steps. In Figure 7 the shear rate is stepped from zero to a finite value ($\dot{\gamma}_1$), following which the viscosity drops exponentially, reaching an equilibrium value. If the shear rate is increased further to $\dot{\gamma}_2$ the viscosity drops again to a new, lower equilibrium value. Now the shear rate is decreased to $\dot{\gamma}_3$ resulting in an exponential rise of viscosity to a higher equilibrium value. If, instead of the multiple steady-shear experiment just described, a shear rate (or shear stress) ramp experiment were to be carried out (Figure 8a), a loop would be observed (Figure 8b). The explanation of the loop is given below, but has to do with the fact that in a ramp experiment the equilibrium structure is never attained. The circuit in Figure 8(b) is called a thixotropic loop. Roughly bisecting the loop is the equilibrium–structure curve generated from the equilibrium viscosity data of Figure 7.

4.4.2 Mechanism of Thixotropy

Thixotropy is defined as “an isothermal, reversible sol–gel (liquid–solid) transformation”.$^{23}$ It is experienced as a viscosity that is both time- and shear-rate (or stress) dependent. Its origin is the breakdown of internal fluid structure to smaller flow units under shear or the reassembly of structure from smaller units, when stress is relaxed. The cause of time dependence is that both breakdown and recovery processes are slow, relative to the rate of change of stress, or to the time of observation at constant stress.

In simple shear thinning or pseudoplastic systems, rapid structural equilibration quickly accommodates to changes in shear rate. The accommodation process essentially is particle diffusion, which is quite rapid for submicron particles (section 5.4.1). The viscosity (a measure of microstructure) thus always keeps up with changes in shear rate for such systems. In contrast, for thixotropic systems, the rate of structural re-organization is slower than the experimental rate of change of shear rate ($\dot{\gamma}$, Figure 8a). In thixotropic systems, a viscosifying structure exists at rest, and the viscosity falls because of the collapse of that structure under shear. This viscosifying structure may consist of, for example, flocculated particulates (flocculated systems will be higher in viscosity than a deflocculated system of the same composition, section 5), an associated network, or may be due to polymers interacting through hydrogen bonds. The necessary attribute of the structure is a significantly long characteristic time (seconds) for breakdown and reassembly. Consequently, on the up side of a shear rate ramp experiment (Figures 8a and 8b), the structural breakdown lags behind the ever-increasing shear rate, so that the viscosity on the up ramp will be higher than the equilibrium viscosity at any given shear rate. On the down side of the ramp, the rebuilding structure lags the reducing shear rate, so that the measured viscosity is always lower than the equilibrium value. Thus, a thixotropic loop is seen, the size of which
should be proportional to the structural time constant, for a given ramp rate and duration. Holding the shear rate constant allows the structural reorganization to catch up until equilibrium between structural breakdown and recovery rates is achieved (as in Figure 7).

4.4.3 Thixotropy Test Methods

4.4.3.1 Thixotropic Index Test The thixotropic index test is very widespread in practice, but a misnomer. The test determines the ratio of viscosities measured at arbitrary high- and low-shear conditions. ASTM test method D2196 specifies taking the ratio of viscosities measured on the Brookfield Synchro-Lectric viscometer at two speeds, representing a 10-fold speed ratio. The test measures only equilibrium viscosities, and therefore provides no information about time dependence and should be called the “shear-thinning index” (STI) instead (it is so named in ASTM D2196). It should be emphasized that thixotropic behavior has two important aspects: shear thinning and time dependence. However, it is the time dependence that makes thixotropy valuable to the formulator. Hence, it is important to correctly characterize the time-dependent aspect of the behavior. For this reason, the so-called thixotropic index test is of limited benefit for characterization of such systems.

4.4.3.2 Thixotropic Loop Method In the thixotropic loop test, a programmed increase and decrease of shear rate (or shear stress) is applied to a thixotropic material (as in Figure 8a), resulting in the generation of a loop (Figure 8b). The size of the loop can be obtained by numerical integration and is taken as an indicator of the rate of structural breakdown and recovery for a given ramp rate (the larger the loop, the slower the breakdown-recovery rates). This method is a difficult one to do correctly, however, and is more complex than it at first appears. The loop size depends on the shear history of the sample (time lapse since previous deformation, manner of sample handling and mounting), the shear rate (or shear stress) maximum in the ramp experiment, and the ramp rate (\(\dot{\gamma}\) or \(\dot{\sigma}\)).

4.4.3.3 Step-shear Method In the step-shear test, a high shear rate (\(10^3 - 10^4\) s\(^{-1}\) preferred) is applied to the material, allowing time for the viscosity (and hence the structure) to reach equilibrium, then the shear rate is suddenly reduced to a very low value (order of 1 s\(^{-1}\); Figure 9). As reassembly of the fluid structure occurs at the low shear rate, the viscosity recovers in approximately exponential fashion. Useful physical parameters can be extracted from the data by fitting the following equation to the recovery curve:

\[
\eta(t) = \eta(0) + [\eta(\infty) - \eta(0)][1 - e^{-t/\tau}]
\]

(20)

In Equation (20) \(\eta(t)\) is the viscosity as a function of time \(t\), \(\eta(0)\) is the sheared-out viscosity (at time zero), \(\eta(\infty)\) is the infinite-time recovered viscosity level, and \(\tau\) is the time constant characterizing the recovery rate. The ratio \(\eta(\infty)/\tau\), is as the recovery parameter (a true thixotropic index), and has been found to correlate well to thixotropy-related properties such as sag resistance and air entrainment. Table 2 gives data for two gel-coat systems, one that sagged excessively and one that did not. The conventional “Thix Index” results do not predict the sag behavior, and in fact are contrary to the observed behavior. The step-shear experimental parameters \(\tau\) and \(\eta(\infty)\) are given, together with their ratio. The nonsagging formula (with additive) has both a shorter recovery time and a higher final recovered viscosity, and the recovery parameter takes both of these into account to predict significantly better sag resistance for the with-additive material.

The step-shear test can be performed on an inexpensive viscometer (such as the Brookfield Synchro-Lectric or Wells-Brookfield Cone/Plate Viscometer) as well as on more sophisticated instrumentation. The latter offer

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|c|}
\hline
Composition & \(\tau\) (s) & \(\eta(\infty)\) (P) & \(\eta(\infty)/\tau\) (P s\(^{-1}\)) & Thix index & Sag? \\
\hline
With additive & 8.9 & 226 & 13 & 4.04 & no \\
Without additive & 18.2 & 97.3 & 5.4 & 5.24 & yes \\
\hline
\end{tabular}
\caption{Gel coat thixotropy test data comparison with step-shear data (\(\tau\) = recovery time constant; \(\eta(\infty)\) = equilibrium recovered viscosity; \(\eta(\infty)/\tau\) = recovery parameter)}
\end{table}

Figure 9 Step-shear method for characterization of thixotropy. The shear rate is stepped down from a high value \(\dot{\gamma}_1\) (emulating application process) to a low value \(\dot{\gamma}_2\) (emulating applied coating layer). The viscosity recovers from zero-time value \(\eta(0)\), characterized by time constant \(\tau\), ultimately reaching equilibrium viscosity \(\eta(\infty)\). The recovery parameter is the ratio \(\eta(\infty)/\tau\).
advantages, of course, particularly viscoelastic characterization capability. The preferred way to characterize thixotropic recovery would be to break down the structure under high, steady shear (as in the step-shear method), then step down to a small-amplitude (small strain) oscillatory-shear test, as described by Dodge.\(^{(25)}\)

The rebuilding of structure can then be followed by means of the viscoelastic parameters (Figure 10), which are sensitive probes of the fluid structure responsible for thixotropy. This method more realistically simulates processes occurring at low strain in the relatively quiet coating layer after application. Figure 11 shows the recovery curves of the viscoelastic moduli \(G'\) and \(G''\) (section 4.6.1) from such a step-shear experiment.

4.5 Plastic (Yield) Behavior

A plastic material has the properties of an elastic solid until a critical stress is applied, whereupon it suddenly yields and becomes fluid. This critical stress is the yield stress, the minimum stress necessary to initiate flow. Ideal plastic behavior includes the following characteristics:

1. Hookean behavior below the yield stress, i.e. the steady-shear viscosity is infinite (or undefined) and the deformation is linear with stress;
2. the yield value is a material constant.

Metals typically exhibit ideal plastic behavior. Ironically, what we commonly call “plastics” (i.e. polymeric materials) do not. For most solid polymeric materials, deformation below the yield point is a combination of elastic strain and viscous flow; hence the measured yield stress is not a material constant but will depend on the deformation history of the material. In a similar way, structured fluids such as paints can exhibit yield-like behavior, apparently changing from solid-like to readily-flowing fluid when a critical stress is exceeded. However, the measured apparent yield stress is not single-valued, but will vary depending on experimental conditions. This is because the interparticle forces (secondary bonds) presumed responsible are of a range of types with a corresponding range of relaxation times.\(^{(26)}\) Therefore, as stress is applied the material undergoes creep accompanied by viscous relaxation, such that some of the secondary bonds rupture before overall yield occurs. As a consequence, the measured yield value will depend on the rate at which the stress is increased up to the point where flow occurs: the faster the rate of stress increase, the higher the measured yield value, and vice versa. For this reason, yield stress values cited in the literature are meaningless unless the exact experimental methodology is provided.

Barnes and Walters\(^{(27)}\) challenged the yield concept with the assertion that most materials with an apparent yield stress will be found, in reality, to have a high but finite viscosity if measured at sufficiently low stresses. Barnes recently published a comprehensive examination of the question.\(^{(28)}\) The idea is that few, if any, structured fluids possess true yield behavior. Although in principle this view is probably correct, it is also true that, in practical terms, yield behavior can have important consequences for the processing, stability, and end-use of materials. There seems to be, from practical experience if not from clear experimental evidence, some sort of rather sudden viscosification (possibly some kind of flow discontinuity) that can occur at low stresses, the magnitude of which is apparently related to the number and strength of interparticle attractive forces.\(^{(26,29)}\) The yield stress is therefore an engineering reality\(^{(30)}\) that must be taken into account when formulating paints or dispersions. A
yield stress may be desirable or undesirable depending on the process in question. Materials with an apparent yield stress will often exhibit thixotropy and viscoelasticity as well.

4.5.1 Static versus Dynamic Yield Stress

The static yield stress is measured by the start-up of flow from rest conditions, by gradually increasing the stress until a finite viscosity is measured. The dynamic yield stress is obtained by reducing the stress on a fluid until it ceases to flow at some nonzero stress value. The method to be used should be chosen with reference to a specific process. For example, for long-term suspension of solids or for start-up flow in pumps, the static yield stress is relevant. Post-application leveling and sag behavior would be governed by dynamic yield stress characteristics, including the kinetics of structural recovery (section 4.4).

4.5.2 Yield Stress Measurement Methods

4.5.2.1 Curve-fitting and Extrapolation Methods

Curve-fitting techniques may be used to obtain a value for the yield stress, by fitting the Bingham, Herschel–Bulkley, or Casson models, for example, to experimental flow data (section 4.1). However, such methods are very questionable because one is attempting to infer a property of the solid state from behavior of the fluid. Limitations of the curve-fitting method are evident in the fact that one usually gets a finite value for \( \sigma_0 \), even when the specimen is clearly a mobile fluid! This begs the question as to whether such extrapolated yield data are very meaningful. Even less satisfactory is the practice of extrapolation of a shear stress–shear rate curve to zero shear rate, taking an intercept on the stress axis as the yield value. Such a method is highly arbitrary and subjective, as well as again being based on the uncertain assumption that the yield stress is related to the fluid viscosity.

4.5.2.2 Start-up of Flow Methods

Penetrometer Method. Start-up-of-flow methods include the use of penetrometer-type instruments such as a thermomechanical analyzer, where increasing force is applied to a probe. The yield stress is determined as the break point of a force–penetration curve.

Controlled-stress Rheometer Method. The controlled-stress (CS) rheometer is well suited to the characterization of the properties of structured fluids, including the yield stress. For this instrument, the applied torque is the independent (or controlled) variable, whereas the dependent (or measured) variable is the angular displacement. With this instrument, the yield stress can be directly measured by a stress ramp experiment. If the stress is gradually increased from zero or a very low value until flow is detected, the instrument then records this value as the measured yield stress. However, it should be remembered that the measured yield stress will be dependent on the experimental protocol, including shear history, ramp parameters, and the test geometry used.

Vaned Rotor Method. A still rather novel technique employs a special vaned rotor to remedy problems of slip in dense suspensions. The vaned rotor consists of rectangular blades or vanes fixed to a rotating shaft. Advantages of this geometry are: (a) there is little disturbance of the sample when this type of probe is inserted; and (b) when the rotor turns, the material moves as a solid cylinder. Thus, the yield surface is within the material itself, avoiding problems of wall slip. Barnes and Carnali showed that the vaned geometry can be used in place of the bob-and-cup geometry for flow curve measurement of shear-thinning fluids.

With the vaned rotor on a controlled-strain-rate (CR) type of rheometer (section 7.2.1.1), the yield stress is measured by monitoring the torque as the geometry is rotated at a constant low rate. The torque will go through a maximum, corresponding to concerted yielding along the virtual cylindrical surface defined by the vane radii. The yield stress is related to the maximum torque \( T_m \) according to Equation (21):

\[
\sigma_0 = \frac{T_m}{K}
\]

where \( K \) is the vane geometric constant given by

\[
K = \frac{\pi D^3}{2} \left( \frac{H + \frac{1}{3}}{D} \right)
\]

In Equation (22) \( D \) is the rotor diameter and \( H \) is the vane height.

Using a CS rheometer, measurement of the yield stress using the vaned rotor is straightforward. The torque is ramped slowly and the stress at which a finite displacement is detected is reported as the yield stress.

4.6 Elastic Liquids (Linear Viscoelasticity)

When a purely viscous fluid is in steady flow, the energy of deformation dissipates as frictional heat. No potential energy is stored. Therefore, viscous flow is an irreversible deformation. Newtonian liquids show essentially ideal viscous (or “inelastic”) behavior over a wide range of deformation rate. For ideal elastic (“Hookean”) substances, all the energy of deformation is stored, similar to a stretched rubber band. Consequently, pure elastic deformation is not permanent, but is in fact completely reversible. Real materials can display a mixture of elastic and viscous character, in varying
degrees. Hence, the term viscoelastic is applied to such materials. In a viscoelastic fluid, elementary flow units interact together in some fashion such that the structural relaxation time (see below) is measurably long. This may be due to a flocculated or percolating particulate structure or to polymeric chain entanglement, for example. As stated, viscoelasticity is a material response that is a combination of viscous and elastic behavior. Viscous flow superimposed on elastic strain results in the relaxation, or gradual disappearance, of stress within the strained object. This is manifested as an imperfect or fading stress memory. Figure 12 illustrates the material response to an applied stress for a material with permanent stress memory, such as a rubber band, and one with fading stress memory, such as “silly putty”. Viscoelasticity can have significant consequences for coatings processes, as discussed in section 4.6.3.

![Figure 12](image1.png)

Figure 12 Stretch–force experiment illustrating viscoelastic stress-memory loss. The rubber band is a cross-linked polymer that does not relax tensile stress ($\sigma_e$) when stretched. The viscoelastic material adjusts to the strain by viscous flow, allowing elastic stress to decay.

![Figure 13](image2.png)

Figure 13 Stress response to oscillatory strain for ideal viscous and elastic bodies. The stress is in phase with the strain for an elastic solid; the stress leads strain by phase shift $\delta = 90^\circ$ for a viscous liquid.

### 4.6.1 Viscoelastic Parameters and their Measurement

Viscoelastic materials are often characterized by sinusoidally alternating the direction of strain (or stress; Figure 13). For example, a sinusoidally varying strain $\gamma$ may be applied at frequency $\omega$ (rad s$^{-1}$). The strain amplitude varies with time $t$ according to Equation (23),

$$\gamma = \gamma_0 \cos \omega t$$

which describes a cosine wave of maximum amplitude $\gamma_0$. The strain amplitude must be small such that the material response remains in the linear viscoelastic region (LVER) where stress and strain are linearly related. In purely elastic behavior (Hookean spring), the stress follows the strain instantaneously; the two are said to be in phase with each other. For materials with a viscous (energy-loss) component in the material response, the stress and strain will not be coincident, but will be out of phase. This happens because viscous flow continually relieves the stress within the material, causing the stress to reach a maximum and die away before the strain maximum. That is, as the rate of strain decreases near the maximum (or minimum) of the strain sine wave, stress relaxation catches up and overtakes the stress-building effect of the strain. The separation of the stress and strain maxima is called the phase shift (or phase angle – the angular part of a complete cycle represented by the phase shift). The phase shift is often given the symbol $\delta$. The faster the viscous stress–relaxation process, the earlier in the cycle the stress maximum will occur, i.e. the larger the phase shift will be. The limiting value of the phase angle for purely viscous liquids is $90^\circ$ (Figure 13). This is because the maximum strain rate (maximum slope of the strain sine wave) occurs $90^\circ$ ahead of the maximum strain, and for Newtonian liquids the stress is proportional to strain rate. Therefore, the maximum stress must occur at the maximum strain rate, which corresponds to a phase shift of $90^\circ$.

The complex shear modulus $G^*$ (Figure 14) is the ratio of the maximum stress $\sigma_0$ to the maximum strain $\gamma_0$, i.e. $G^* = \sigma_0/\gamma_0$. The complex modulus $G^*$ may be

![Figure 14](image3.png)

Figure 14 Viscoelastic relationships in a complex plane.
separated into $G'$, the modulus of elasticity (storage modulus), and $G''$, the viscous modulus (loss modulus). Figure 14 demonstrates the geometric relationship of $G''$ to its in-phase and out-of-phase components, $G'$ and $G''$, governed by the phase angle $\delta$. It is obvious from geometry that when $\delta$ is zero, $G'' = G'$, and when $\delta = 90^\circ$, $G'' = G'$. The physical meaning is that, when $\delta = 0$, the mechanical response is purely elastic, whereas when $\delta = 90^\circ$, the response is purely viscous. Trigonometry yields Equations (24) and (25):

\[
G' = G'' \cos \delta \quad (24)
\]
\[
G'' = G'' \sin \delta \quad (25)
\]

Put another way, $G'$ is the component of the complex shear modulus that is in phase with the strain. $G'$ therefore represents the elastic part of viscoelastic behavior. $G''$ is the viscous component of the modulus, the part that is $90^\circ$ out of phase with the strain, but in phase with the strain rate (i.e. in phase with the velocity).

We can define a dynamic viscosity $\eta'$ as the quotient of the stress in-phase with the strain rate divided by the strain rate:

\[
\eta' = \frac{\sigma_0 \sin \delta}{\gamma_0} = \frac{\sigma_0 \sin \delta}{\gamma_0 w} = \frac{G' \sin \delta}{w} = \frac{G''}{w} \quad (26)
\]

Equation (26) is obtained using the relationships $\gamma_0 (\text{strain-rate amplitude}) = \gamma_0 w$ and $G' = \sigma_0 / \gamma_0$. (The angular frequency $w = 2\pi f$ (f in hertz).)

The magnitudes of $G''$ and $G'$ reveal the relative importance of viscous and elastic behavior in the mechanical response of a material. In Figure 14, again by trigonometry, the tangent of the phase angle equals the ratio $G''/G'$. Thus, $\tan \delta$ quantifies the balance of energy loss and energy storage, measured under certain conditions of temperature, pressure, and frequency or rate of deformation. For solids, $\tan \delta$ can be useful in predicting the likelihood of brittle or ductile failure of a polymer or the sound absorption or vibration-damping properties. For liquids, $\tan \delta$ can monitor the progress of fluid restructuring in thixotropic recovery. The latter may be useful in computing sag resistance, for when $\tan \delta$ becomes less than unity the system has essentially become immobilized (i.e. it has reached a dynamic yield point). When $\tan \delta > 1$, viscous flow (i.e. a steady-state viscosity) is possible. However, when $\tan \delta < 1$ the material is more elastic than viscous and can be regarded as a gel.

### 4.6.2 Models for Linear Viscoelasticity

It is useful to employ simple mechanical models as aids to conceptualizing linear viscoelasticity. As stated, viscoelasticity is a combination of two idealized behaviors: Hookean elasticity and Newtonian viscosity. The mechanical analog of Hookean behavior is a spring of force constant $G$, and that of Newtonian flow is a dashpot – a piston-in-cylinder filled with a viscous fluid of viscosity $\eta$. These elements are combined in various ways to model viscoelastic response.

The first model consists of a spring and dashpot in series (Figure 15), an arrangement known as the Maxwell model. To imagine what response the model has, apply a constant stress $\sigma_0$ to one end, the other being fixed. The dashpot is considered to be infinitely long, so that the piston never runs out of travel. This being the case, an equilibrium strain would never be reached, but the dashpot would continually move as long as the stress is applied. As the model can flow without limit, this is obviously a model for viscoelastic liquids (also called elasticoviscous liquids). The foregoing describes a creep experiment, in which a sudden stress $\sigma_0$ is applied, and the evolution of strain, or deformation, is followed with time. The creep of a Maxwell liquid is not very interesting, however. As Equation (27) shows, the Maxwell strain–time curve consists merely of a straight line with intercept equal to $\sigma_0/G$ and slope of $\sigma_0/\eta$:

\[
\gamma = \frac{\sigma_0}{G} + \frac{\sigma_0 t}{\eta} \quad (27)
\]

An alternative to the creep method, that is useful for viscoelastic solids, is to apply a sudden deformation and follow the decay of stress with time. This is similar to the experiment depicted in Figure 12 and is known as stress relaxation. A sudden strain $\gamma_0$ results in instantaneous lengthening of the spring. The dashpot experiences an initial stress $\sigma_0$ from the extended spring, causing a gradual movement of the dashpot’s piston, relaxing both the spring and the stress. Figure 16 illustrates the decay of stress in a stress relaxation experiment for the Maxwell model, described by Equation (28):

\[
\sigma = \sigma_0 e^{-Gt/\eta} \quad (28)
\]

The quotient $\eta/G$ has the dimension of time; this quotient is given the symbol $\lambda$ and is referred to as
the stress-relaxation time constant. It can be seen from Equation (28) that when \( t = \eta / G \), then \( \sigma = \sigma_0 / e \).

Therefore, \( \lambda \) represents the time for the stress to fall to 1/e of its initial value (Figure 16). The time constant \( \lambda \) could also be called the stress memory time constant, as it is the time taken for a viscoelastic material to forget its initial elastic stress level when subjected to a constant strain.

In modern rheometers, sinusoidal oscillation is a common method of viscoelastic characterization. Equations (29–31), derived for the Maxwell model,\(^{39,40}\) show how the viscoelastic time constant \( \lambda \) may be obtained from the oscillatory data:

\[
\eta' w = G' = \frac{G_{\infty} w \lambda}{1 + w^2 \lambda^2} \tag{29}
\]

and

\[
G' = \frac{G_{\infty} w^2 \lambda^2}{1 + w^2 \lambda^2} \tag{30}
\]

from which,

\[
\tan \delta = \frac{G''}{G'} = \frac{1}{w \lambda} \tag{31}
\]

where \( G_{\infty} \) is the limiting value of \( G' \) reached at high frequency, equal to the Maxwell spring constant. Equation (31) says that where \( G' \) and \( G'' \) cross over (\( \tan \delta = 1 \)), then \( \lambda = 1 / w_c \) (\( w_c \) is the cross-over frequency). The high-frequency modulus can be obtained from Equation (30), because at the cross-over point \( G_{\infty} = 2G' \). Similarly, at cross-over, the zero-frequency plateau viscosity \( \eta = 2\eta' \) [from Equation 29].

If the mechanical elements are connected in parallel rather than series, they each experience identical strain, but the stresses are now additive. This arrangement is called the Kelvin–Voigt model (Figure 17). Because the elements are now in parallel, the Kelvin–Voigt model can only undergo finite strain, limited by the extensibility of the spring. Therefore, this is a model for a viscoelastic solid below its yield point. Equations (32–34), for creep, stress relaxation, and \( \tan \delta \), for the Kelvin–Voigt model are

\[
\gamma = \frac{\sigma_0}{G} (1 - e^{-t/\lambda}) \tag{32}
\]

\[
\sigma = \gamma_0 G \tag{33}
\]

\[
\tan \delta = \frac{1}{\omega \lambda} \tag{34}
\]

These equations describe an exponentially increasing strain at constant stress (see Figure 18 and Equation 32) and a nonrelaxing stress at constant strain [Equation 33], respectively.

The Maxwell and Voigt models each have a single relaxation time and cannot accurately describe viscoelastic materials that have multiple relaxation mechanisms and associated relaxation times. A model must possess multiple elements in order to describe them. A Maxwell element connected in series with a Kelvin–Voigt element is a first step in that direction, and does indeed model the linear viscoelasticity of real systems better than the single element models. Figure 19 shows such an arrangement, known as the Burgers model. Equations (35) and (36) describe creep and stress relaxation behavior for the
Figure 19 Burgers model: subscript 1 refers to the Voigt element; subscript 2 refers to the Maxwell element.

Burgers model:

\[ \gamma = \frac{\sigma_0}{G_2} + \frac{\sigma_0 \ell}{\eta_2} + \frac{\sigma_0}{G_1} (1 - e^{-t/\lambda_1}) \]  
(35)

\[ \sigma = \gamma_0 G_2 e^{-t/\lambda_2} + \gamma_0 G_1 \]  
(36)

where \( \lambda_1 = \eta_1/G_1 \) and \( \lambda_2 = \eta_2/G_2 \). The creep and stress relaxation behaviors for the Burgers model are shown in Figures 20 and 21. Modern rheometers of the controlled stress type are capable of performing creep measurements. Creep data are usually analyzed according to an extended Burgers model, to which has been added a series of additional Voigt elements.

4.6.3 Viscoelasticity and Industrial Processes

The role of elasticity in an industrial process depends on the rate (or frequency) of deformation. Put another way, the response of a viscoelastic material depends on how long a stress is applied (1/\( \omega \)), relative to the time required for any elastic extra stress to decay. This suggests taking a ratio of the stress relaxation time constant \( \lambda \) to the time (duration) of the process stress, \( t \). This ratio is a defined rheological term known as the Deborah Number,

\[ De = \frac{\lambda}{t} \]  
(37)

It is named for the Biblical prophetess Deborah, who prophesied that the “mountains flow before the Lord”.

This is an accurate statement, long before being verified by the science of geology, of the fact that, on God’s timescale, rock formations can be observed to undergo permanent deformation, or flow. In other words, if the duration of the applied stress \( t \) greatly exceeds the relaxation time \( \lambda \) (\( De \ll 1 \)) the material will respond as a viscous fluid (because elastic stress has time to decay). Conversely, if \( De \gg 1 \) a material behaves as if an elastic solid. When \( De \approx 1 \) the material will behave viscoelastically (i.e. stress relaxation will take place on the timescale of the process). Thus, the Deborah number quantifies the proportion of elastic to viscous control of a process. This is one reason why a determination of the viscoelastic properties of paints and coatings is important. An equivalent way of writing the Deborah number is Equation (38),

\[ De = \frac{\lambda \dot{\gamma}}{\gamma} \]  
(38)

where \( \dot{\gamma} \) is the shear rate of a coating process. As an example of how the role of elastic extra stress can be determined for a given process, assume a stress relaxation time constant of about 10 s for a paint. Thus, for a pigment particle settling at \( \dot{\gamma} \approx 10^{-5} \text{s}^{-1} \), \( De \ll 1 \) and the paint would offer no elastic resistance to the settling pigment. However, for leveling (\( \dot{\gamma} \approx 0.1 \text{s}^{-1} \)), \( De \approx 1 \) and elastic stress is likely to retard the leveling process.
Viscoelastic dispersions\(^{(42)}\) and associative polymer solutions\(^{(43)}\) can show Maxwellian behavior with a single relaxation time. In general, however, real materials may not exhibit simple exponential stress decay (i.e. a single relaxation time), but rather may possess a spectrum of relaxation times. However, the mechanical response can be dominated by the longest relaxation time,\(^{(36)}\) obtained from experiments such as described in foregoing sections.

The process consequences of viscoelasticity are also partly due to the stabilization of otherwise unstable liquid structures by the elastic extra stress. Thus, liquid fibers and webs which would ordinarily collapse due to surface tension are stabilized, leading to, for example, rollocot spatter\(^{(44)}\) (or misting) and ribbing, and also inhibiting atomization of sprayed materials. Once again, the Deborah number gages the importance of viscoelasticity for a particular process. Of course, both the magnitude and lifetime of the elastic stress will be important, for together they will govern the degree of stabilization.

Many processes, particularly of coatings application, involve large strains outside the range of linear viscoelastic behavior. There is no general theoretical basis for treatment of nonlinear viscoelasticity at present. However, there are promising experimental methods, based on an enhanced creep analysis, for characterizing nonlinear viscoelastic behavior, even at high frequencies.\(^{(45)}\) It may be possible to build experimental correlations between nonlinear viscoelasticity and coatings performance.

### 5 RHEOLOGY OF DISPERSIONS

Rheology is particularly useful for dispersion characterization because of its sensitivity to the microstructure. Both the stability and quality of dispersions can be evaluated. Dispersion rheology has two broad aspects: (a) the dependence of viscosity on the concentration of the dispersed phase, and (b) the dependence of viscosity on shear stress and shear rate. (A third important aspect is the viscoelastic properties of dispersions, which will not be discussed here.) Additional factors are particle shape, rigidity, particle size and size distribution, and interparticle forces, both attractive and repulsive. All these elements combine to determine the microstructure of the dispersion, its response to stresses, and hence its rheology.

A dispersion consists of a discontinuous phase dispersed within a continuous phase (often mobile). For example, this might be a system in which a fine-particle-size solid is wetted by, and thoroughly mixed with, a liquid. The dispersed phase may be a liquid (emulsions), solid (suspensions), or gaseous (foam). The terminology is somewhat inconsistent in the literature, but the dividing line between colloidal dispersions and less-stable dispersions that it seems logical to call “suspensions” is, in practical terms, one of particle size. Colloidal particles range in size from about 10 nm to 1 \(\mu\)m. Due to their small size and mass, colloidal particles often are very slow settling, or are nonsettling, because Brownian motion effectively keeps them suspended. However, even colloidal-size dense particles will eventually settle. Suspensions above 1 \(\mu\)m in size generally exhibit rapid settling because Brownian forces are ineffective with such massive particles. Van der Waals attractive forces are proportional to particle size, and so larger particles tend to flocculate, leading to more rapid settling.

Addition of a particulate phase to a liquid increases its viscosity in proportion to the volume fraction \(\phi\) of the dispersed phase. \(\phi\) is the fraction of the total volume of the dispersion occupied by the dispersed material (a dimensionless number; Equation 39):

\[
\phi = \frac{\text{volume of particles}}{\text{volume of dispersion}}
\]

A convenient way of expressing the effect of a dispersed phase on the viscosity of a liquid is by normalizing the dispersion viscosity to the pure-liquid viscosity. This ratio is termed the relative viscosity \(\eta_r\) and is also dimensionless [Equation 40]:

\[
\eta_r = \frac{\eta_d}{\eta_l}
\]

The contribution of a single particle to the viscosity of a dispersion is characterized by its intrinsic viscosity (or limiting viscosity number) \([\eta]\), a function of particle shape and deformability. \([\eta]\) is obtained as the slope of a plot of \(\eta_r - 1\) (formerly known as the specific viscosity) versus \(\phi\) [Equation 41]:

\[
[\eta] = \lim_{\phi \to 0} \frac{\eta_r - 1}{\phi}
\]

It is reasonable that the viscosity of a liquid will be augmented by a factor equal to the product of the particle intrinsic viscosity and the concentration of particles [Equation 42]:

\[
\eta_r = 1 + [\eta]\phi
\]

Einstein\(^{(46)}\) calculated the intrinsic viscosity for noninteracting rigid spheres in a Newtonian liquid, obtaining the number 2.5 [Equation 43]:

\[
\eta_r = 1 + 2.5\phi
\]

The intrinsic viscosities of other particle shapes, such as prolate and oblate spheroids (discs and rods), have been calculated\(^{(47)}\) and are always greater than 2.5. This
It is also seen in Figure 22 that predicts a finite viscosity at Equations (43) and (44). It can be seen that Equation (44) and shows curves corresponding to the predictions of for actual dispersions (using the data of Eilers at a volume fraction considerably less than unity. The value of such that the dispersion can no longer flow. The value of , the density of particle packing is such that the dispersion can no longer flow. The value of will be system dependent (also shear-rate dependent) and will be determined by particle shape, particle size distribution, the ionic strength of the medium, the degree of particle flocculation, and the manner in which the particles arrange themselves (pack) in three-dimensional space.

Numerous models have been proposed containing . Probably the most successful in fitting a variety of data is the Krieger–Dougherty model [Equation 45]:

\[
\eta_t = 1 + 2.5\phi + 6.2\phi^2
\]  

Figure 22 illustrates the typical dependence of \( \eta_t \) on \( \phi \) for actual dispersions (using the data of Eilers), and shows curves corresponding to the predictions of Equations (43) and (44). It can be seen that Equation (44) predicts a finite viscosity at \( \phi = 1 \), which is not realistic. It is also seen in Figure 22 that \( \eta_t \) goes toward infinity at a volume fraction considerably less than unity. The volume fraction \( \phi_m \) corresponding to \( \eta_t \rightarrow \infty \) is called the maximum volume fraction, or maximum packing fraction. At \( \phi = \phi_m \), the density of particle packing is such that the dispersion can no longer flow. The value of \( \phi_m \) will be system dependent (also shear-rate dependent) and will be determined by particle shape, particle size distribution, the ionic strength of the medium, the degree of particle flocculation, and the manner in which the particles arrange themselves (pack) in three-dimensional space.

Figure 22 shows the fit of the Krieger–Dougherty model to data of Eilers, using a value of \( [\eta] \) close to the Einstein value. The maximum packing fraction will have different, unique values at low and high shear rates because the strength of the shear field determines how efficiently particles pack together. Reviews of the rheology of polymer colloids are recommended for further reading.

Having said that dispersion viscosity depends on the disperse-phase volume fraction \( \phi \), it is often the case that the effect of the particle phase on the rheology may be greater than expected on the basis of the volume of material used to make up the dispersion. This is because it is the hydrodynamically effective particle volume fraction that determines the rheology, rather than the formulated volume fraction. Thus, the rheological behavior will scale with the effective volume fraction, \( \phi_{eff} \), rather than with the formulated volume fraction, \( \phi \).

There are two mechanisms that can cause \( \phi_{eff} \) to be greater than \( \phi \). In the first, the effective particle radius increases as a consequence of various methods of dispersion stabilization. For example, adsorption of a polymeric stabilizer onto the surface of a particle adds the thickness of the stabilizer layer to the particle radius. By steric–osmotic interactions between stabilizer layers, the close approach and flocculation of particles is prevented, resulting in steric stabilization. If the thickness of the steric stabilizing layer on the particle is \( \delta \), the effective volume fraction is given by Equation (46),

\[
\phi_{eff} = \phi + \left( \frac{\delta}{R} \right)^3
\]  

where \( R \) is the original particle radius. Quantitative viscometric methods have been developed for inferring the adsorbed-layer thickness.

The effective particle radius and hence the effective volume fraction \( \phi_{eff} \) can also be increased by the effects of particle electrical charge. Aqueous dispersions are often stabilized by association of repulsive electrical charge with the particle, which is called electrostatic stabilization. The charge may be due to adsorbed ions, anionic or cationic surfactants or polyelectrolytes, or, as in the case of polymer colloids, to the presence of ionizable groups which are part of the polymer molecules. (In the case of functionalized polymer latexes, such groups tend to migrate to the particle surface.) The surface ionic charge surrounds the particle with an electrical field, which propagates into the aqueous phase at a
distance inversely proportional to the ionic strength of the medium. In the presence of dissolved counterions, an ionic atmosphere envelops the charged particle. These phenomena are the origin of the so-called electroviscous effects, which have to do with the way the electrical field surrounding the particle affects the collision cross-section and the effective volume fraction, and also the nature of the hydrodynamic interaction between particle and surrounding liquid.\(^{47,55}\) The rheology of a dispersion can be greatly altered as a consequence of these effects, as the solution ionic strength or the pH are varied. In a study by Krieger and Eguiluz, \(\eta_r\) for a dispersion of uniform polystyrene latex spheres (\(\phi = 0.4\)) decreased from \(10^9\) to 10, as the result of increasing the concentration of electrolyte by two orders of magnitude.\(^{56}\) In that study, the low-electrolyte latexes exhibited apparent yield stress behavior, a consequence of the increase of the effective volume fraction of the latex particles due to the expansion of the repulsive electrostatic field. The effect is so great that the particles become locked into crystalline arrays that can diffract light, producing striking iridescent colors. As the electrolyte concentration is increased, the counterion cloud both shrinks the electrostatic field and shields particle fields from each other. Consequently, the viscosity drops dramatically (remember that the volume change depends on the cube of the radius change).

A second mechanism by which \(\phi_{\text{eff}}\) can exceed \(\phi\) is flocculation. When particles form flocs, the liquid phase contained within the interstices of the floc is not free-draining, but effectively becomes part of the floc. Thus the volume of a flocculated phase is augmented by the volume of trapped interstitial liquid. Consequently, the dispersed-phase volume fraction is higher than for the deflocculated system.

Dispersions can exhibit the full range of rheological behavior mentioned previously, including Newtonian, shear-dependent, time-dependent, plastic, and elastic behavior. A dispersion of noninteracting spherical particles will be Newtonian up to about \(\phi = 0.2.\)\(^{16}\) Above this point, onset of non-Newtonian character begins due to particle interactions and hydrodynamic factors. Mechanisms for these effects are discussed in section 4.2.

### 6 RHEOLOGY OF FILM FORMATION

In the following sections two coating flows, sagging and leveling, are described. These flow processes occur in an applied coating layer during what is known as the film-formation phase of drying. In describing the way in which the coating rheology controls the flow, there is an important point to be made. Both sagging and leveling are driven by specific shear stresses, which can be calculated from the forces acting (gravity and surface tension, respectively) and the geometry of the film. However, these processes can occur over a wide range of shear rates, depending on the coating’s viscosity at the acting shear stress. For this reason it is preferable to graph flow behavior as viscosity versus shear stress plots, as opposed to viscosity versus shear rate, which is the more common practice. The shear rate is the dependent variable, for real processes. The appropriate independent variable to use to differentiate the performance of paints according to their rheology is the shear stress. Not to do so is wrong in principle and will result in incorrect relative ranking of paints by their rheology with respect to their rates of sagging, leveling, pigment settling, or to their ease of application. The discussion below neglects much in the way of detail, which can be found in an earlier review.\(^{57}\) The focus is on the former issue, as it is key to using rheological data correctly in the interpretation of flow curves.

Plotting with shear stress as the independent variable (Figure 23) allows straightforward and correct comparison of paints at the specific shear stress for a particular process. The process stresses illustrated here are for (a) gravity-driven sagging of a 3-mil wet film, (b) surface tension-driven leveling of surface roughness, and (c) application by brush or roller. The point is that, no matter what the rheology of a paint, the shear stress acting on a coating layer for a given process is the same (for a given geometry, density, surface tension). The shear rates for these processes, however, are not the same, as shown in Figure 24. Figure 24 shows the same two paints as in Figure 23, this time with the viscosity plotted as a function of shear rate. Note that process shear rates are shifted to the left for the higher viscosity paint.

![Figure 23](image-url) Viscosity versus shear stress plot for two paints A (●) and B (○). Vertical dashed lines indicate gravitational shear stress driving sagging for a 3-mil wet paint layer; surface-tension-driven leveling stress; brushing/rolling application stress.
6.1 Sagging

On a non-horizontal substrate, a liquid coating layer will flow or drain downward under the influence of gravity. For a coating on a vertical wall, this is usually called sagging. Sagging is driven by gravitational shear stress \( \sigma_g \) which is due to Smith et al. (62) and others (67, 68) have discussed the importance of Marangoni flows for coatings. Overdiep (62) showed that a strong Marangoni rebound occurs during the leveling of solvent-based paints which develop surface tension gradients during drying. Nevertheless, predictions of relative sagging behavior, particularly if the flow curves cross over. In contrast, when plotted as a function of shear stress (Figure 23), the sagging shear stresses are single vertical lines, unambiguously cutting the viscosity curves at the value appropriate to the particular situation.

6.2 Leveling

A freshly applied coating layer will be of variable thickness, having a pattern of surface roughness generated by hydrodynamic factors in the application process. It is desirable to have uniform coating thickness for both esthetic and functional reasons. The process of smoothing of the initial rough surface is driven by surface tension and is called leveling. Numerous studies of the subject have been published (56, 58–64) but the role of rheology and other factors in the leveling of paint films is not fully understood. One might expect leveling to correlate reasonably well to low-shear viscosity. However, factors such as viscoelasticity, time-dependent viscosity, evaporation, wicking, and surface tension gradient flows make leveling a complex process. These complications are not dealt with here, but a fuller discussion of leveling and sagging is available in an earlier review (57).

The basic model for the leveling of a thin liquid layer is due to Smith et al. (65) Orchard later (66) developed a complicated expression for the leveling of a more realistic, arbitrarily rough surface profile in terms of a Fourier series. However, the expression simplifies considerably when the coating thickness is assumed to be small relative to the roughness wavelength. Assuming a single sinusoidal wavelength (which is a reasonable approximation as the leveling behavior will be dominated by the longest wavelength), the Orchard equation is

\[
\ln \frac{a_t}{a_0} = -\frac{16\pi^4 h^3 \gamma t}{3\lambda^4 \eta} \tag{48}
\]

for constant surface tension \( \gamma \) and viscosity \( \eta \). Equation (48) says that the roughness amplitude \( a_t \) decays exponentially with time as a function of the coating layer thickness \( h \) to the third power and of the inverse roughness wavelength \( \lambda \) to the fourth power.

The Orchard equation is a deficient model for the leveling of real paints because it assumes Newtonian fluid behavior and neglects time-dependent effects, such as thixotropy, viscosity increase due to drying and wicking, and surface tension gradient (Marangoni) effects. Overdiep (62) and others (67, 68) have discussed the importance of Marangoni flows for coatings. Overdiep (62) showed that a strong Marangoni rebound occurs during the leveling of solvent-based paints which develop surface tension gradients during drying. Nevertheless,
progresses.

A roughness wavelength proceeds.

drying on viscosity during the leveling period is neglected, the method still suffers from the limitation that the effect of streaming or linked methods. However, the foregoing is accomplished by employing a rheometer capable of job-section 4.4.3. This kind of procedure is most easily characterized as necessary input.

6.2.1 Rheological Measures of Leveling

Kornum and Raaschou–Nielsen advocate rheological test conditions which simulate real paint processes, i.e. the best rheotest for leveling should most closely simulate the application and postapplication experience of the paint. This would mean that: (a) the paint should experience shear rates/stresses/strains similar in magnitude and duration to those of the application process; (b) the shear rate/stress/strain should then be step-changed to values representative of the leveling process; (c) the change of viscosity or viscoelasticity with time should then be followed under the latter conditions. This protocol is essentially identical to the step-shear method of characterizing thixotropic recovery described in section 4.4.3. This kind of procedure is most easily accomplished by employing a rheometer capable of job-streaming or linked methods. However, the foregoing method still suffers from the limitation that the effect of drying on viscosity during the leveling period is neglected, and that the leveling stress decays with time as leveling proceeds.

Equation (49) calculates the stress driving leveling from the roughness amplitude $a$, roughness wavelength $\lambda$, wet film thickness $h$, and surface tension $\gamma$:

$$\sigma_{lev} = \frac{8\pi^3 \gamma ah}{\lambda^3}$$

(49)

This leveling stress decays exponentially as leveling progresses. The variation of viscosity with decaying shear stress can be characterized using a CS rheometer with programmable logarithmic stress ramp. Leveling efficiency might then be judged by numerically integrating the fluidity over the leveling period [Equation 50]:

$$\Phi = \int_0^1 \frac{1}{\eta} \, dr$$

(50)

Leveling and gloss have been found to be logarithmic functions of the fluidity integral for powder coatings.

7 RHEOLOGY INSTRUMENTATION

7.1 Industrial Viscometers

Many different instruments have been devised to measure viscosity or consistency in the industrial laboratory. However, a number have serious design limitations that make them generally poorly suited for the measurement of non-Newtonian fluids. This becomes an important issue when one realizes that paints and other commercial products such as pastes, slurries, dispersions, emulsions, gels, etc. are non-Newtonian. The problem with many of the familiar laboratory viscometers is that the flow field is complex and not subject to mathematical analysis. The result is that an accurate stress or strain rate cannot be calculated. Therefore, the true viscosity cannot be known. Furthermore, the nonuniformity of the shear field causes the viscosity of the material to vary within the test specimen for non-Newtonian materials. For complex flow fields, such an error cannot be corrected. The measurement error will be in proportion to the sample’s deviation from Newtonian character. A second important deficiency of most simple viscometers is a lack of temperature control, which can be a source of significant error. These quality-control viscometers have been discussed elsewhere and are not further considered here.

7.2 Absolute Viscometers

An absolute viscometer produces viscometric flow (steady simple shear) and yields data in absolute units for non-Newtonian fluids. Broadly, these are of two types: rotational viscometers and efflux viscometers. Rotational viscometers employ steady (uniform) shear, oscillatory shear, and transient (time-dependent) shear experiments of various types. Efflux viscometers extrude the fluid through a small-gap orifice, which can be a capillary tube, a slit, or an annulus (concentric cylindrically walled tube). Absolute devices based on acoustic wave propagation exist, but are less common. The focus in this abbreviated treatment will be on rotational instruments. Several other instruments capable of absolute measurement are being excluded from discussion because of a limited range. These include the Brookfield viscometers, the falling needle viscometer, the ICI cone and plate viscometer, and others. A number of summaries of other instrumentation and methods are available. Although dated, Van Wazer et al.’s book is still a useful resource.

7.2.1 Rotational Instruments

7.2.1.1 Controlled Stress and Controlled Rate

The choice of working principles in modern rotational rheometers is between controlled strain (or controlled
straining rate) and controlled stress. The difference is whether the torque or the angular displacement is the controlled variable. In a controlled-strain instrument the angular displacement (or perhaps angular velocity) is the independent (controlled) variable and the opposing viscous torque the dependent (measured) variable. Controlled-stress instruments control the torque, and measure the resulting rate of angular displacement. Instruments of the controlled-strain type include the Weissenberg Rheogoniometer, Haake CV, Rheometrics ARES, and Bohlin CVO. Instruments of the CS type include the TA Instruments AR-1000, Rheometrics SR5, Bohlin CSR, Haake RS, and Physica MC rheometers.

Each instrument type has characteristic advantages and limitations. The choice between the two types of instrument depends on the material under test and the intended experiments. In terms of performance, CS instruments can measure much lower angular velocities than can CR instruments, but CS tend to be more limited at the high angular velocity and oscillation frequency end. Both CS and CR instruments have inertia issues affecting the accuracy for high frequency or rapid accelerations. In the case of CS the issue is measurement system inertia and is correctable; for CR the problem is torque system resonance and is not correctable. The CS type is better suited to measure long relaxation times. (75)

CR instruments impose a shear-rate sweep while measuring the drag-torque response of materials. Structured fluids tend to be shear-sensitive (more precisely, strain-sensitive). Consequently, as strain increases exponentially under a linear strain-rate sweep protocol, the fluid structure tends to collapse rapidly, with the result that relatively few data points are obtained to provide information on structure. In contrast, CS devices use linear (and logarithmic) rates of stress increase, an intrinsically gentler mode of deforming materials, which allows materials to obey their own rules of stress–strain response. CS instruments are especially useful for characterizing structured fluids, such as paint, printing ink, adhesives, ceramic slips, coal slurries, cement, pigment and colorant dispersions, drilling muds, medicines, foodstuffs, cleaners, personal care products and cosmetics, solder pastes, etc. This is particularly true where materials exhibit yield behavior. In principle, CS instruments can directly measure the stress at the onset of yield, avoiding errors associated with extrapolation or curve-fitting methods (section 4.5.2.2).

Considering coating flows as a case in point, it is important to realize that the proper variable for correlating coating rheology to real-world coating processes is the shear stress, not the shear rate. First of all, coating flows are the outcome of the sum of forces acting on a fluid coating layer. That is, the rheological response to those forces determines the resulting coating flow. Therefore, coating flows are not driven at a given shear rate, but rather the observed shear rate is the result of the stress driving the process and the corresponding viscosity at that stress. Using stress as the applied variable is, in this sense, the more natural way to characterize coatings.

Both CS and CR instruments each do their own version of a transient experiment: creep for CS and stress relaxation for CR. The stable torque and high strain resolution capabilities of CS mean creep experiments can be used to probe very slow relaxation processes. A modified creep method—a programmed series of small torque increments—can be used for determining the first Newtonian plateau down to very low shear rates (section 5.4.2). A limiting factor in the accuracy of such methods, however, is the ability to minimize or correct for spurious air-bearing torque.

7.2.1.2 Inertia Correction One of the issues in CS rheometry is errors due to inertia. If the test fluid is low in viscosity, and/or the test rotor has a large moment of inertia, and/or the acceleration is too high (short ramp time), the applied torque is partially expended to accelerate the mass of the measuring system. This is the cause of “bell-mouth” loops in flow curve ramp experiments. Krieger has published a correction method for this error. (76) Commercial CS instruments now feature on-line inertia correction.

8 RHEOMETRY: EXPERIMENTAL METHODS

Rheometry is the experimental aspect of rheology. A rheometer is an instrument that can suitably measure some rheological property, or material function (section 3.2), such as the viscosity as a function of shear rate or shear stress. Normally, a curve will be produced representing the functional dependence of the measured property. In contrast, a viscometer will generally measure viscosity at a single (sometimes even unknown) value of the shear rate (or shear stress), or perhaps over a very limited range of values. These types of devices are typically found in the industrial quality control or formulation laboratory, and have been discussed previously. (77) This section focuses on techniques for the use of rotational rheometers to characterize fluids with complex rheological properties.

8.1 Rotational Rheometry

Simple shear deformation was defined in section 2.2, in which a fluid is confined between surfaces that are in parallel, rectilinear motion (i.e. a sliding plate rheometer). However, very few rheometric instruments utilize this test
geometry. This is because it is not a practical geometry, as either the experiment must be rather short in duration, or one of the shear faces must be very long. This predicament is solved by using rotational motion to shear a material between, say, a fixed plate and a rotating disk. The majority of commercial rheometers operate thus, using a variety of rotating fixtures or geometries, mainly (a) cone and plate, (b) parallel plate, and (c) concentric cylinder (bob and cup). Detailed descriptions of these standard geometries are available.\(^{39,77--79}\)

Another important test geometry used in steady-shear flow is tube flow or capillary rheometry. Its use is somewhat limited outside the characterization of polymer melts, and consequently is not discussed further here.

One novel geometry that offers some advantages in measuring difficult materials, particularly those exhibiting wall slip is the vaned rotor.\(^{33,34}\) It consists of rectangular vanes fixed to a rotating shaft (section 4,5.2). Barnes and Carnali\(^{35}\) have shown that, for sufficiently shear-thinning fluids, this geometry is equivalent to a conventional bob and cup, except that wall slip is avoided because the effective shear surface is within the fluid itself, not at a solid surface.

Three principal rheometric techniques are typically used for rotational rheometers:

1. steady shear (large strain) – for equilibrium viscosity measurement, nonequilibrium viscosity measurement, and normal stress measurement;
2. creep (medium strain);
3. oscillation (small strain).

### 8.1.1 Steady Simple Shear (Equilibrium Viscosity)

Steady simple shear involves a uniform flow field in which the shear rates and stresses are independent of position. Not all rheometer test geometries meet this criterion exactly, but they do generally satisfy the requirements of viscometric flow, defined by Dealy and Wissbrun\(^{80}\) as a flow field that is “everywhere indistinguishable from steady simple shear” (but not necessarily uniform shear). Viscometric flow is a necessary requirement in order to properly measure material functions.

Some rotational rheometers utilize steady-shear equilibrium viscosity measurements to characterize flow behavior, by means of a series of shear rate steps. If, for example, a constant torque is applied to a specimen until a constant shear rate is observed (after inertial and structural relaxation effects have equilibrated with time), the system is undergoing steady simple shear and the steady-state viscosity or equilibrium viscosity can be measured. (Even with thixotropic materials, it should be possible to observe a steady-state viscosity value eventually.) An equilibrium flow curve (as in Figure 3) can be generated in this way.

### 8.1.2 Time-dependent Materials: Nonequilibrium Flow Curve

As mentioned, one can construct a curve of equilibrium viscosity versus shear rate or shear stress by a series of step-equilibrium experiments (a variant of the creep test, see below). However, the nonequilibrium flow curve is less time-consuming experimentally and perhaps more informative with regard to the processability of time-dependent materials. The nonequilibrium flow curve is obtained by recording the viscosity while the angular velocity or torque is ramped, or increased with time (usually followed by a decreasing torque or velocity ramp; Figure 8a). Time-dependent effects such as hysteresis can be seen in this way (Figures 8b and 25). The collapse of the structure and also relaxation effects can be seen, which are lost in an equilibrium measurement. Figure 25 shows a flow curve for a structured fluid, measured by a stress-ramp procedure with the curves corresponding to the increasing-stress and decreasing-stress ramps indicated.

#### 8.1.2.1 Shear-history Effects: Sample Mounting and Conditioning

A great many industrial and commercial materials possess time-dependent rheology, usually thixotropy, but occasionally antithixotropy (section 4.4). Time-dependent materials pose a special set of challenges to the experimentalist, and it is easy to make mistakes in characterizing them. For time-independent systems the pre-experiment shear history is unimportant. In contrast, the shear history of time-dependent materials prior to the experiment will influence the results.

Both the degree of deformation in mounting a sample and the time elapsed since mounting will affect the rheological state of a time-dependent material and hence the experimental results. Failure to take account of this issue often leads to poor repeatability of data on such systems. Some approaches to control this shear-history problem are:

![Figure 25](attachment:viscosity_vs_shear_rate.png)

**Figure 25** Viscosity versus shear rate curve for a thixotropic paint done by a stress-ramp experiment. Up ( ) and down ( ) ramp data are indicated.
1. Controlling the rate of closure of the platens in a parallel-plate or cone-plate experiment (e.g. exponentially decreasing the closure rate).

2. Allowing a rest time for the sample after mounting (limited by evaporation and productivity issues).

3. Giving a controlled shear history to the sample, such as preshearing the specimen for a set period, then initiating the experiment immediately on cessation of shear. (An up–down ramp cannot be applied in this case, because the sample would begin to recover in an uncontrolled way concurrent with the initial low-shear ramp onset. Instead, a series of step reductions from high shear can be applied, with the time delay between steps being varied, in order to simulate the effects of varying degrees of structural recovery.)

Method (1) reduces the strain rate (but not the strain) the sample experiences as the instrument gap closes, but will be limited in its effectiveness because practical rates of closure (plus the coupled deformation) are likely to be significant in terms of their effect on the specimen’s structural integrity. Furthermore, depending on the geometry (e.g. cone and plate) the strain may not be uniform. Method (2) is limited by the time one can afford to wait for structure recovery. It is not uncommon for a material to require hours in order to regain its rest-state condition. The use of an arbitrary rest time is a compromise that provides a practical but not ideal method of characterizing thixotropic materials. Method (3) is somewhat arbitrary, too, in that it is not known a priori at what shear stress or shear rate or for how long a material must be preconditioned in order to achieve adequate or consistent structural breakdown. Whatever the method chosen, it is important to adhere strictly to a constant protocol if results are wanted on a comparable basis.

8.1.2.2 Ramp Methods

Many rotational rheometers have the ability to apply a time-based ramp of torque or angular velocity for purposes of flow-curve measurement. Some allow a choice of either a linear time-based ramp or one that is logarithmic with time. The latter method spaces the data points very close together in the initial ramp, which increases the amount of information obtained at low shear rates and stresses, but also imparts a different shear history. For time-dependent systems, it is as important to keep the experimental conditions constant as to keep the pre-experiment shear history constant, in order to obtain repeatable results and to assure valid comparison of materials. This means keeping the following experimental settings constant for a given series of experiments:

1. ramp duration;
2. choice of linear or log time-based ramp;
3. maximum shear stress (or shear rate);
4. duration of any hold-time at ramp maximum.

8.1.3 Transient Methods

Transient methods are nonsteady state, i.e. the stresses, strains, and material properties are not at equilibrium, and it is their behavior as a function of time that is being studied, as they move toward equilibrium. Transient methods include:

1. step shear stress (creep and recovery);
2. step shear strain (stress relaxation);
3. step shear rate (thixotropic recovery);
4. start-up of flow

The first two methods are briefly discussed in section 4.6.2. The third method is described in section 4.4.3. The last method will not be discussed here. We will now discuss creep methods in more detail.

8.1.3.1 Creep Methods

The viscoelastic character of a material can derive from a range of molecular and/or particle interactions, each with their individual force constants, length scales, and dissipative characteristics. Viscoelastic deformation can therefore occur over a range of strains and stresses. Another consequence is that viscoelastic materials will display a range of relaxation times, sometimes referred to as a relaxation spectrum. An oscillatory shear or dynamic method for determining linear viscoelastic behavior (sections 4.6.1 and 8.2) has a practical lower limit of frequency $\omega$, due to the time required to complete an oscillation at very low frequencies. Since the Deborah number $De = \lambda/\omega = w_{\lambda}$, the measurement of very long relaxation times $\lambda$ (characteristic of polymers) would necessitate the use of very low frequencies – probably below the practical limit (we do not want to wait hours to complete enough oscillations to analyze). An answer to this is the creep method, in which a constant stress $\sigma_0$ is applied to a material, which then undergoes strain. Creep conveniently probes long relaxation timescales, but also short- and intermediate-time behavior, as well.

As described in section 4.6.2, in a creep-recoil shear experiment a stress $\sigma_0$ is suddenly imposed and the evolution of strain is followed with time. This initial phase of creep is one of retarded compliance and is characterized by retardation time constants. Retardation data can be represented as strain $\gamma$ versus time or as creep compliance $J$ versus time. The complex shear compliance $J^*$ is the quotient of the strain and the stress (the inverse of the complex shear modulus $G^*$). Being the inverse of the modulus, a material of higher compliance is less rigid,
or softer [Equation 51]:

\[ J^*(t) = \frac{\gamma(t)}{\sigma(t)} \tag{51} \]

Equation (35) gives the relationship between strain \( \gamma \) and time for the Burgers model (Kelvin–Voigt element and Maxwell element in series), and Figure 20 shows the corresponding creep curve. Dividing Equation (35) through by the stress, gives Equation (52) for the time-dependent creep compliance as a function of time \( t \):

\[ J(t) = \frac{1}{G_2} + \frac{t}{\eta_2} + \frac{1}{G_1}(1 - e^{-t/\eta_1}) \tag{52} \]

or, expressed only in terms of the compliance [Equation 53],

\[ J(t) = J_2 + \frac{t}{\eta_2} + J_1(1 - e^{-t/\eta_1}) \tag{53} \]

where the subscripts refer to Figure 26.

Real materials will generally have a spectrum of relaxation times; hence a general form of Equation (53), an extended Burgers model, is given by Equation (54) for \( n \) Voigt elements:

\[ J(t) = J_0 + \sum_{i=1}^{n} J_i(1 - e^{-t/\eta_i}) + \frac{t}{\eta_0} \tag{54} \]

where \( J_0 \) is the instantaneous compliance and \( \eta_0 \) is the equilibrium Newtonian viscosity reached at long times. Figure 26 shows a representation of a general creep mechanical model corresponding to Equation (54), for \( n = 2 \). A test for linear viscoelasticity is that \( J(t) \) is independent of \( \sigma_0 \). A rule of thumb is that one viscoelastic unit is needed per decade of experimental frequency.

A property of Voigt units is that they cannot move for ever, i.e. individually, they are not capable of continuous flow. The spring will lengthen under stress, retarded by the viscous dissipation represented by the dashpot, but will reach an equilibrium extension and stop. The rate of lengthening of a given Voigt element is given by \( \eta/G \), the ratio of the dashpot viscosity to the spring constant, called the retardation time. In a real material, represented by a series of Voigt elements, the Voigt element with the shortest retardation time (with a low viscosity and/or high rigidity) reaches equilibrium deformation first and then ceases to move. Further movement of the material is due to the remaining Voigt elements as they approach their own equilibrium deformation, in order of increasing retardation time. If the applied stress is greater than the “yield stress” (in quotes because of the uncertain nature of the concept), then springs will start to break and the system will achieve steady flow, described by the single dashpot \( \eta_0 \) (the Newtonian viscosity). When steady-state flow (steady-state compliance) has been achieved in the retardation step, the stress \( \sigma_0 \) is removed and, if any elastic stress remains, the system will recover some strain, or show recoil (Figure 27). The recovery curve can be fitted by a recoil function or by an extended Burgers model analysis as above.

8.1.3.2 Analysis of Nonlinear Viscoelasticity Using Creep

Viscoelastic materials are not only sensitive to the rate of strain but also to the total strain. Thus, there is a critical strain beyond which the material response is nonlinear (non-Hookean), in which the springs are breaking (i.e. the structures or interactions responsible for the elastic character are breaking down). Such a system displays nonlinear viscoelasticity, for which a general theoretical model is lacking. The equations describing linear viscoelastic behavior are invalid in the nonlinear regime, thus oscillatory methods are normally restricted to the linear regime. However, few real-world processes for either coatings or other commercial fluids actually take place within the linear regime. Many processes are high strain or even infinite strain, and therefore the nonlinear viscoelastic properties will govern the material behavior. Creep offers a way of characterizing materials in the nonlinear, as well as the linear, regime.

In a creep experiment a torque is suddenly applied to the specimen (or suddenly removed, in the recovery step).

Figure 26 Generalized Burgers model for creep retardation analysis corresponding to Equation (54) for \( n = 2 \).

Figure 27 Showing elastic recoil or recovery after removal of the stress \( \sigma_0 \).
The sudden acceleration, together with the measurement system’s inertia, causes a strain overshoot, and for viscoelastic materials this can result in viscoelastic ringing, where the material undergoes a damped oscillation just like a bowl of jello that is bumped (Figure 28). The oscillations can be rather short-lived, and may not be apparent unless the time axis is logarithmic. Normand and Ravey\(^{82}\) showed that this coupling between the instrumental inertia and material elasticity can be analyzed according to standard viscoelastic models. They also found that this modified creep analysis can both replace standard forced oscillation methods and extend the accessible frequency beyond the typical range of such methods. Baravian and Quemada\(^{45}\) have shown in addition that the method can be used to characterize nonlinear viscoelasticity and to separate the effects of thixotropy from viscoelastic relaxation.

8.2 Oscillatory Shear

If, instead of applying a strain (or, interchangeably, stress) in a constant direction, the direction of the strain undergoes cyclic reversal, then the specimen is subjected to oscillatory deformation, sometimes also referred to as a dynamic test (section 4.6.1). (Note that it is immaterial whether the independent variable is the stress or the strain, for oscillatory linear viscoelastic measurements. Wherever the discussion mentions stress, one may equally well read strain.) Most commercial rotational rheometers are capable of oscillatory shear using a variety of test geometries, although there is now available an oscillatory compression rheometer for liquids, utilizing the parallel plate geometry (TA Instruments CP-20). Oscillatory tube flow has also been used for dynamic testing.

Oscillatory testing is normally done in the linear viscoelastic regime, where the stress and strain are related by a linear differential equation. The usual practice is to employ sinusoidal variation of strain or stress. Testing modes in oscillation include:

1. torque sweep or strain sweep at constant frequency;
2. frequency sweep at constant strain;
3. time or temperature sweep at constant frequency.

Oscillation is a convenient way of characterizing the medium to short timescale response of viscoelastic materials, in the LVER. The employment of small strains (below the critical strain for the LVER) at low frequencies is a reasonable simulation of the physical state of a newly applied coating layer in the process of film formation. Hence, the low-frequency linear viscoelastic properties of coatings are of interest in understanding this phase of coating performance, especially if measured subsequent to a high-shear high-strain experience.

8.2.1 Torque Sweep/Strain Sweep

Torque sweep on a CS rheometer or strain sweep on a CR rheometer are used to determine the strain sensitivity of the viscoelastic parameters, and thus determine the critical strain $\gamma_{cr}$, which is the strain limit for linear viscoelastic response. The elastic modulus $G'$ is a sensitive indicator (more so than the dynamic viscosity) of the breakdown of structure, and is often used to determine the critical strain. The experiment is done by applying a constant frequency (e.g. 1 Hz) while increasing the torque gradually, so that the strain amplitude steadily increases. Modulus $G'$ will be constant within the linear viscoelastic regime. The critical strain is the point where $G'$ begins to decrease (Figure 29).
The strain is then held constant at the critical value for subsequent frequency sweep experiments, ensuring that the deformation remains within the linear regime.

The critical strain is not a single value for a given material, however, but is a decreasing function of frequency, a consequence of the superposition of viscous and elastic response to deformation in a viscoelastic material. At lower frequencies, the material can undergo more strain due to viscous flow, without fracturing. However, a plot of $G'$ versus oscillatory stress shows that the critical stress increases with frequency.\(^{(83)}\)

This behavior is analogous to the observation that the measured yield stress value is an increasing function of the rate of loading, and in fact the mechanisms underlying the two effects are identical.

Polymeric systems can have quite large critical strains (above 10\%), whereas $\gamma_c$ for colloidal systems can be quite small (below 0.1\%). The critical strain value is a measure of the brittleness or ductility of the microstructure, and an indicator of the relative length scale of the forces responsible for the elastic behavior.

Difficulty is often encountered in finding the linear regime for thixotropic materials composed of flocculated or associated particles, because the structure is rather brittle – the attractive forces are short range, and the critical strain is consequently small.

8.2.2 Frequency Sweep

In a frequency sweep experiment, the oscillation frequency is steadily increased, while the strain is held constant below the critical value. Typically, the frequency is swept logarithmically with time, so that the discrete frequency points are linear on a log axis. A typical plot of viscoelastic functions for a frequency sweep experiment is shown in Figure 30. $G'$ and $G''$ normally increase with frequency, whereas $\eta'$ decreases with frequency, trends which can be understood by examination of the mechanical models’ response. As pointed out in section 4.6.2, values for the viscoelastic functions can be obtained from frequency-sweep data, e.g. the frequency, $\omega_c$, where, $G'$ and $G''$ cross, equals the inverse of the relaxation time (in the Maxwell model). A gel is distinguished by having a nearly constant value of $G'$ with frequency, since a gel will not have a finite relaxation time.

Frequency sweep experiments are in some ways analogous to the flow curve measured in steady shear. In fact, the empirical Cox–Merz rule asserts the equivalence of steady shear rate and angular frequency in oscillatory deformation. The Cox–Merz rule means that steady shear and oscillatory data should be superimposable, and typically works well for polymeric materials. However, the rule generally fails for colloidal or particulate systems, because the average microstructure during the period of oscillation is not representative of that achieved in steady shear, due to the rapid structural equilibration of such systems. The value of the Cox–Merz rule is probably greatest for characterization of polymers, as an answer to the problem of elastic artifacts (such as the Weissenberg effect), which usually limit the steady shear rate for entangled polymer melts to around 1 s\(^{-1}\). By use of the rule, one can extend polymer steady shear data to higher shear rates using oscillatory data. A modified Cox–Merz rule, called the Rutgers–Delaware rule,\(^{(84)}\) apparently works for dispersions, provided the structural recovery time constant is slow relative to the period of oscillation. The microstructure must equilibrate to that characteristic of steady shear at an equivalent effective maximum dynamic shear rate. This effective maximum dynamic shear rate is determined from the maximum strain rate amplitude [Equation 55]:

$$\dot{\gamma}_{\text{max}} = w\gamma_0 = \dot{\gamma}_{\text{eff}} $$  (55)

8.2.3 Time or Temperature Sweep

A time sweep at constant frequency is used to characterize recovery of structure after shear, such as for a thixotropic material (section 4.4.3.3). Emulsion stability can be indicated by temperature sweep experiments at constant frequency.\(^{(85)}\) An oscillatory temperature sweep is an excellent way to characterize the chemical advancement of thermosetting polymers, a technique used in a subdiscipline known as chemorheology (the study of the rheology of chemically reacting systems).\(^{(85,86)}\)

8.2.4 Experimental Protocol

Similar to the discussion of shear-history effects (section 8.1.2.1), the rheological state of a specimen is of concern, with an eye to obtaining repeatable results.
Consequently, the following series of experimental steps is recommended:

1. The specimen should be prior-sheared in steady shear at an arbitrary high shear rate or stress value, to put the specimen in a low-structure state.

2. A constant-frequency small-strain oscillatory time-sweep step should be commenced immediately, following the structural recovery to a constant-property state, if possible.

3. Once the specimen has recovered to equilibrium properties, either of two experiments can be done:
   
   (a) oscillatory frequency-sweep experiment;
   
   (b) steady-shear flow curve ramp experiment.

The above protocol is a logical sequence which enables tests to be done on a specimen which is in a repeatable rheological state.

8.2.5 Linearity

As discussed above, the test of linearity in the viscoelastic response is that the rheometrical functions $G^\prime, G^\prime\prime, \eta^\prime$ are independent of the strain amplitude or stress amplitude. When they cease to be constant, the critical value of stress or strain has been exceeded. Another manifestation of nonlinearity is that the response function contains not only the fundamental exciting frequency $\omega$, but also harmonics of the fundamental.

LIST OF SYMBOLS

- $\Phi$ fluidity integral
- $\beta$ time constant characteristic of a transition shear rate
- $\gamma$ dimensionless shear strain; surface tension
- $\dot{\gamma}$ shear strain rate ($s^{-1}$)
- $\delta$ phase shift; thickness of adsorbed polymer layer
- $\eta$ coefficient of viscosity
- $\eta_0$ zero-shear viscosity
- $\eta_\infty$ high-shear limiting Newtonian viscosity
- $\eta_d$ dispersion viscosity
- $\eta_l$ liquid-phase viscosity
- $\eta_r$ relative viscosity ($\eta_d/\eta_l$)
- $\eta^\prime$ dynamic viscosity
- $[\eta]$ intrinsic viscosity (limiting viscosity number)
- $\theta$ angle of inclination with respect to the vertical
- $\lambda$ wavelength of coating surface striations; elastic stress relaxation time constant
- $\pi$ ratio of circumference of a circle to its diameter
- $\rho$ density
- $\sigma$ shear stress; generalized stress
- $\sigma_0$ yield stress; stress at zero-time
- $\sigma_e$ tensile stress
- $\phi$ volume fraction of internal (dispersed) phase of a dispersion
- $\phi_{\text{eff}}$ effective volume fraction for a dispersion
- $\phi_m$ maximum packing fraction of a dispersion, where $\eta \rightarrow \infty$
- $w$ angular frequency ($=2\pi f \text{ rad s}^{-1}$)
- $A$ area of shear face
- $De$ Deborah number ($\lambda/\tau$)
- $F$ force
- $G$ shear modulus
- $G_\infty$ plateau modulus
- $G^\ast$ complex shear modulus
- $G^\prime$ storage modulus
- $G^\prime\prime$ loss modulus
- $K$ consistency in power law model
- $R$ universal gas constant; spherical particle radius
- $T$ absolute temperature
- $T_g$ glass transition temperature
- $a$ curvature parameter in Equation (16)
- $a_t$ amplitude of coating surface striations at time $t$
- $a_0$ time-zero amplitude of coating surface striations
- $e$ base of the natural logarithmic scale = 2.71828
- $f$ frequency
- $g$ gravitational acceleration (cm s$^{-2}$)
- $h$ film thickness
- $k_B$ Boltzmann’s constant
- $l$ length
- $n$ power law exponent
- $t$ time
- $v$ velocity
- $x$ coordinate parallel to surface
- $y$ coordinate normal to surface

# Thermal Analysis of Coatings

Edwin F. Meyer III  
*ICI Paints Research Center, Strongsville, USA*

## 1 Introduction

The thermal analysis of coatings involves measuring the response of a material when subjected to a thermal stimulus, sometimes in combination with a mechanical stress. The thermal stimuli used in the thermal analysis of coatings include linear temperature ramps, a sinusoidal modulation around a fixed temperature, the superposition of a linear ramp and a sinusoidal modulation, and a simple isotherm in which some property of the material is monitored as a function of time. The responses measured by the thermal analyst include: melting, crystallization, evaporation, degradation, stress relaxation, softening point, and glass transition, as well as physical properties such as the elastic and viscous moduli. These responses aid in the development, characterization, and determination of the proper application and bake conditions for a wide range of coatings.

In general, thermal analysis techniques are very sensitive and, for many applications, a sample mass of the order of 10 mg is sufficient. However, the assignment of a thermal event to a particular chemistry or morphology requires knowledge of the system being analyzed or another analytical technique. For example, thermal analysis can accurately determine the temperature and enthalpy of a crystalline polymer melt but it does not provide any other information as to the chemistry of the polymer. Assigning a cause to a thermal event becomes increasingly difficult as the nature of the material becomes more complicated. Such is the case with a fully formulated coating which contains a wide range of polymeric and oligomeric materials, as well as various additives. To determine which chemistry is responsible for a particular thermal transition, other analytical techniques are used, frequently in direct combination with the thermal analysis technique.

## 1 INTRODUCTION

The end users of coatings often demand that a particular product meet specifications that involve end-use properties, such as: water resistance, scrub resistance, detergent resistance, flexibility, hardness, impact resistance, and degree of tackiness. Besides these requirements of the final coating, there are also application-related criteria that have to be met. These include low-temperature film formation, the degree of cure at a given time and temperature, and the time taken to dry. All these specifications can be related back to fundamental chemical and physical properties of the coating, using thermal analysis. In general, thermal analysis is simply the characterization of the properties of a material as a function of temperature. This definition is frequently expanded to include isothermal experiments performed on conventional thermal analysis instruments. Standard techniques include differential scanning calorimetry (DSC), thermogravimetric analysis (TGA), dynamic mechanical analysis (DMA), and others.

(DMA), dielectric analysis (DEA), and thermomechanical analysis (TMA). Variations on these techniques include modulated temperature differential scanning calorimetry (MTDSC) and modulated thermogravimetric analysis (MTGA). In these two techniques the temperature program of the sample is modulated, which provides superior results in virtually all cases.

Recent advances in thermal analysis include microthermal calorimetry. This technique involves the marriage of modulated temperature spectroscopy and atomic force microscopy (AFM) by effectively placing a modulated temperature probe on the tip of an AFM probe.

2 DIFFERENTIAL SCANNING CALORIMETRY

2.1 History

A great step toward modern DSC was achieved in 1899 by William Chandler Roberts-Austen, then chemist to the Royal Mint, when he conceived the idea of measuring the temperature difference between the sample and a thermally inert material. Previously, all attempts at determining the heating curve for a material – at that time mostly clays and minerals – involved only the measurement of the temperature of the material as a function of time. The advantage of the differential method is twofold. First, a differential method is more precise and, second, the differential method eliminates the need to use time as a dependent variable. That is, the differential method produces a \( \Delta T \) vs \( T \) curve, where \( T \) is the temperature of the material and \( \Delta T \) is the temperature difference between the material and the thermally inert reference.

From this time until very recently the advances toward modern DSC were mainly instrumental. For example, better temperature measurement and control, control of the atmosphere within the cell, and a greater symmetry between the sample and reference positions. Another great leap forward in DSC came in 1992 when Dr Mike Reading, then of ICI Paints, conceived the idea of superimposing a modulation on top of the linear sample temperature rate. Prior to this development the linear temperature rate performed two functions: to supply the temperature difference between the sample side and the reference side and the temperature regime of interest. A modulation of the temperature of the sample side can supply a useful temperature difference between the two cell positions, allowing the experimentalist to independently adjust the rate at which the temperature regime of interest is scanned. Indeed, the temperature scan rate or linear underlying temperature rate can be set to zero. The technique of modulating around a fixed temperature and monitoring the output signal as a function of time has been called quasi-isothermal MTDSC. Of course, modulating the temperature of the sample side will produce a modulated temperature difference between the sample and reference. This modulated temperature difference acts as a continuous probe of the heat capacity of the sample – irrespective of any kinetic events occurring within the sample. If the heat capacity of the sample increases, the amplitude of the thermal energy transfer between the furnace and the sample, needed to produce the programmed temperature modulation, will increase proportionally. This change in the amplitude of the thermal energy transfer will be manifest in the temperature difference between the sample and the reference.

2.2 Differential Scanning Calorimetry Fundamentals

The technique of DSC is used to detect and quantify thermal events in a material. These thermal events include glass transitions, melts, crystallizations, stress relaxations, chemical reactions, and volatilizations. The working part of the instrument is the cell (Figure 1). The cell contains two sites – sample and reference – and is enclosed by a furnace block that, ostensibly, is thermally symmetric with respect to the sample side and reference side. Thermocouple junctions just underneath each position monitor both the temperature of the sample side, \( T_{\text{sample side}} \), and the difference between the temperature of the sample side and the temperature of the reference side, \( T_{\text{ref side}} - T_{\text{sample side}} \). If the cell is empty and thermally symmetric, the temperature of the reference side will always be the same as the temperature of the sample side, irrespective of the manner in which the furnace block is heated or cooled.

To perform a typical DSC experiment a sample is placed in a small aluminum pan and the pan is then placed on the sample side. To thermally balance the pan

![Figure 1](image)

Figure 1 Simple diagram of the DSC sample cell. The output signal is the temperature difference between the sample side and the reference side.
containing the sample, an empty, identical reference pan is placed on the reference side.

With this configuration any temperature difference between the reference side and the sample side can be attributed solely to the presence of the sample. Further, it can be shown – assuming Newton’s law of cooling describes the thermal energy transfer – that this temperature difference is directly proportional to the rate of thermal energy transfer between the furnace and the sample.

2.3 Sample Preparation

A thermal analyst for a coatings company can divide all sample submissions into two groups, commercial and research. Research samples are usually less problematical because their history is well known – the samples have been prepared and baked on-site. Commercial samples offer a different set of challenges because the coating has been applied at the customer’s site under line conditions that are usually not as well controlled or as well characterized as those in a research center.

For this reason, when trouble-shooting a problem with a commercial coating it is important to obtain a coating sample directly from the substrate upon which the problem occurred. For example, if the thermal analyst is to trouble-shoot a film-whitening problem on the exterior of tuna fish cans at a plant in Ecuador, it is important that he/she analyzes coating taken directly from a can that exhibited the film-whitening. The reason for this is twofold. First, the coating may have changed from the time it left the facility where it was manufactured and when it was applied and, second, virtually all the physical properties of the coating are a strong function of the bake conditions.

One method of obtaining a coating that has been baked on a substrate is simply to carefully scrape off a small amount with a bladed instrument. Ideally, the sample mass for a DSC experiment is about 5 mg, although lighter samples can be used. The thinner the coating, the larger the area that must be scraped to obtain a massive enough sample. In the case of interior beer and beverage coatings, which can be as thin as 2 µm, about 25 cm² of coating will need to be removed to obtain a 5 mg sample. The scrapings from the coating are placed in a cylindrical aluminum pan which, typically, is about 1 mm high and 5 mm in diameter. To optimize the thermal energy transfer, the sample should be spread out evenly in the pan. To ensure good thermal contact between the sample and the pan, an aluminum lid is placed on top of the sample and then crimped with the pan, thus forming a aluminum sandwich with the sample. If the sample may contain volatiles, it is good practice to make a hole in the pan lid before crimping. This will prevent a pressure increase inside the sample pan during heating.

One problem that may arise when scraping a coating from a soft metal is that some metal is scraped off with the coating. This will make the results nonquantitative because the total mass of the sample does not represent the mass of the coating. However, the results will be qualitative and, in many cases, this is good enough.

2.4 Experimental Conditions

For both linear temperature differential scanning calorimetry (LTDSC) and MTDS the technician must choose a purge gas and a flow rate. The purge gas, which should be inert, will displace moisture and oxygen in the DSC cell and assist in the transfer of thermal energy between the furnace, the reference, and the sample. Although helium, due to its high speed at a given temperature, provides a more efficient thermal energy transfer, nitrogen is conventionally used for virtually all standard applications. For specialized applications where fast heating rates or high modulation amplitudes are used, helium may be used. A typical nitrogen flow rate is 50 cm³ min⁻¹, but this can be adjusted based on the type of sample being run and the programmed temperature rate of the sample.

Another experimental parameter that is common to both LTDSC and MTDS is the temperature range. For optimum results it is common practice to choose a starting temperature that is at least 50 °C before any transition and, of course, the final temperature should be sufficiently above any transitions of interest.

The lone experimental parameter that is the reason for the difference between LTDSC and MTDS is the temperature rate. In LTDSC the operator selects only the linear temperature rate which is constant throughout the run. This temperature rate creates the steady-state temperature difference between the temperature of the sample side and the temperature of the reference side – in other words the output signal. So, a higher temperature rate provides a higher signal-to-noise ratio. Unfortunately, because the linear temperature rate is also the mechanism by which the temperature regime of interest is scanned, a high temperature rate tends to broaden the transitions and thus meld transitions that are close to each other. Often, when running an LTDSC experiment, the operator must compromise between sensitivity and precision.

In MTDS the temperature difference between the sample side and the reference side – the output signal – can be generated solely by the modulation, leaving the operator free to choose a linear temperature rate that will scan the temperature regime of interest at a slower rate. Choosing the temperature protocol in an MTDS experiment requires the assignment of three parameters: the underlying linear temperature rate, the temperature modulation amplitude, and the period of the temperature modulation. The first consideration when assigning these parameters is whether the furnace is able to carry out the
modulation. If the period is too small or the amplitude too high for a given linear temperature rate, the actual temperature rate of the sample side will not follow the set protocol. That is, the sine wave will be distorted. A typical set of MTDSC temperature parameters may be an underlying heating rate of \(2^\circ\text{C/min}\), a modulation amplitude of \(1^\circ\text{C}\), and a modulation period of 1 min. If a faster underlying temperature rate is desired, the modulation amplitude may have to be lowered or the period of the modulation raised to ensure that the furnace can keep the sample-side temperature on protocol. A simple technique to check whether the sample-side temperature is a sine wave is to plot the modulated temperature of the sample side versus time.

### 2.5 Applications

In most coatings applications the desired result from a DSC experiment is the \(T_g\) (glass transition temperature; or \(T_g^s\)) of the polymer system. The \(T_g\) of a polymer is an important parameter for coatings formulators because it gives an indication of the processing conditions needed in manufacturing, the application conditions needed to produce a film from the wet coating, as well as the performance properties of the final film. Due to the complexity of today’s coatings, the characterization of the \(T_g\) of a particular coating system can be confounded by various thermal events. These include surfactant melts and crystallizations, stress relaxations, volatilizations, and all kinds of rearrangements of the polymer micromorphology with temperature – especially near to the \(T_g\) of one of the components. For this reason, MTDSC is the method of choice for coatings analysts. Also, MTDSC can separate the heat capacity of the coating from kinetic thermal events. A simple example that demonstrates this involves a pilot plant batch and a laboratory batch of a resin.

One of the problems frequently encountered by plant engineers is the scale-up of a reaction. Frequently, a resin made in a 1 gal laboratory reactor will exhibit different physical properties to one made in a 10 000 gal pilot plant reactor, even though the recipe was the same. This is because larger reactors often have different heat flow and mixing characteristics. When the product from two different reactors are significantly different, the thermal analyst is often called upon to characterize the two resins. Figure 2 shows the total heat flow versus temperature for two samples – one manufactured in a 1 gal laboratory reactor and the other manufactured in a 100 gal pilot plant reactor. Here the assignment of \(T_g\) is problematical due to kinetic events near the \(T_g\) transition. The heat capacity and its derivative are shown in Figure 3. Here the assignment of \(T_g\) is a trivial matter, using the peak in the derivative curve. Clearly, the samples have different \(T_g\) values.

**Figure 2** The total heat flow versus temperature curves for a pilot plant batch and a laboratory batch of a particular coating.

**Figure 3** The heat capacity and its derivative versus temperature from the same experiment shown in Figure 2.

Another advantage MTDSC offers over LTDSC is sensitivity. In LTDSC the temperature scan rate through a region of interest must be kept high in order to produce a useful temperature difference between the sample and the reference sides. This precludes the accurate characterization of many minor thermal events. The first example that demonstrates the enhanced sensitivity of the MTDSC protocol involves the emulsion polymerization of vinyl acetate (VA) and of butyl acrylate (BA) monomers with a ladder of concentrations. The ladder consists of five evenly spaced steps from 50/50 VA/BA to 90/10 VA/BA. The samples were prepared by drawing down the emulsion and allowing it to dry for three days.

**Figure 4** A coplot of the heat capacity and its derivative with respect to temperature plotted versus temperature for the 90/10 concentration ratio. Here there is a sharp transition and an easily defined \(T_g\). The 80/20 results, shown in Figure 5, exhibit a major \(T_g\) from the copolymer and a minor \(T_g\) from VA homopolymer (ca. 40°C). The VA homopolymer was from the pure
Figure 4 The heat capacity and its derivative for a 90/10 blend of VA/BA.

Figure 5 The heat capacity and its derivative for a 80/20 blend of VA/BA.

Figure 6 The heat capacity and its derivative for a 50/50 blend of VA/BA.

Figure 7 The total heat flow curves for a latex taken at three different ageing times.

Figure 8 The derivative of the heat capacity curves for the runs shown in Figure 7.

VA seed used in manufacturing the emulsion. The results from the 50/50 sample are shown in Figure 6. Here four transitions are evident, identified as follows: the VA/BA copolymer (ca. −10 °C), the VA seed (ca. 40 °C), a small amount of BA homopolymer at about −50 °C and a small transition at about 25 °C, due to the region of interpenetration between the VA seed and the VA/BA copolymer.

A second example that demonstrates the sensitivity of the MTDSC technique involves the homogenization of a latex with time. It is well known that a latex paint continues to cure for a couple of weeks after it is applied, even though it is dry to the touch after a few hours. Coatings manufacturers can characterize this slow ageing with MTDSC. Figure 7 shows the total heat flow traces for a latex sample at 4, 11 and 23 days after application. Due to the kinetic activity, the \( T_g \) is obscured. However, the derivative of the heat capacity traces, shown in Figure 8, is free from the kinetic activity that confounds the total heat flow. From the gradual melding of the peaks with ageing time it can be imagined that the coating is becoming more homogeneous with time.
determination of the relative concentration of each monomer in a copolymer. An unknown sample was suspected to be a copolymer of only two monomers, monomer A and monomer B. The first experiment performed was to determine the $T_g$ of the unknown. Next tested were three concentration ratios that were polymerized from monomer blend ratios of 100/0, 50/50, and 0/100. From a plot of the $T_g$ versus concentration ratio using only these three points, the estimated ratio of the unknown was about 84/16. To check this, three samples were prepared with concentration ratios of 80/20, 85/15, and 90/10. These results confirmed the original estimate of 84/16 as the concentration ratio of the unknown. A coplot of all the MTDSC results is shown in Figure 9 and a plot of $T_g$ versus concentration ratio is shown in Figure 10. The curve in Figure 10 is that calculated from the Fox equation and the horizontal line represents the $T_g$ of the polymer with the unknown monomer blend ratio.

Whereas most coatings sold to consumers are air-dried, most commercially applied coatings are baked. The optimal bake for a given coating is often bounded on both sides. An underbake can result in a weak, soft, and permeable coating, whereas an overbake can result in a brittle coating that has a tendency to crack. Avoiding an overbake is especially important when the coating used in a precoat, postforming application. In such a process flat metal stock is coated and baked. Following this, the pieces are stamped and formed from the coated metal. Many food cans, such as those used for soup, tuna, vegetable, and fruit are manufactured using the precoat postform process. The $T_g$ of a coating can be a strong function of bake temperature and thus an indicator of the bake a coating received. The following example involves a corrosion problem with an interior food coating at a customer’s plant. To investigate this complaint, bake extremes were prepared in the laboratory and compared with the coating taken directly from a problem can. The temperature derivative of the heat capacity results is shown in Figure 11. Clearly, the $T_g$ is a function of bake and thus can be used as the $T_g$ of a coating baked at a customer’s plant as an indicator of the bake it received at the customer’s plant.

The degree to which the $T_g$ of a coating is a function of the bake depends upon the nature of the coating. The $T_g$ of a thermoplastic coating increases with bake due to the loss of plasticizing agents, such as water, whereas the increase in the $T_g$ of a thermoset coating during a bake is due mainly to an exothermic cross-linking reaction which transforms a low-molecular-weight liquid into an infinite network. The rate of the cure reaction will be
limited by the reactivity of the components when its temperature is below its $T_g$, and limited by diffusion when it has vitrified. However, as the $T_g$ is changing due to cross-linking, a thermoset system may – if the conditions are right – vitrify, devitrify, and then revitrify. That is, a chemical reaction causes the $T_g$ to exceed the temperature of the coating and the coating vitrifies, thus drastically altering the rate of reaction. Then the oven brings the coating above its current $T_g$, where the reaction rate will again be governed by the reactivity ratio of the components. Finally, the cure proceeds to a point where the $T_g$ again exceeds its temperature and the coating revitrifies. To optimize the efficiency of a thermoset cure it is helpful to know the $T_g$ of the coating as a function of the degree of cure and the reaction rate of the components as a function of temperature. With such information the plant engineers can set the temperatures at various zones in the oven in a manner that minimizes the time the coating is in the oven and thus maximizes the efficiency of the oven.

To obtain these parameters requires access to the $T_g$ as a function of time during the cure reaction. This makes it an ideal candidate for interrogation with MTDSC which can separate the heat capacity signal from the exotherm due to the cure reaction.

Indeed, MTDSC has been used to fully characterize the bake of a thermoset coating.\(^1\)\(^2\) Note that this is virtually impossible with LTDSC because the relatively small $T_g$ transition is difficult to deconvolute from the larger exotherm.

Another application of DSC to coatings involves the detection of additives – specifically waxes. These lubricants are added to industrial coatings for a variety of reasons. They provide slip during the metal-forming process in precoat postform applications, they provide smooth transport through the trackwork that transports the work throughout the plant and they act as an interior release agent in food cans – so the food slides out of the can easily. There are a tremendous variety of commercially available lubricants which range from natural carnauba wax to Teflon\(^\text{®}\). The identification of a wax is accomplished not through its $T_g$ but through its melt temperature. Because of this it is not necessary to run MTDSC – a linear temperature rate can be used. One application where DSC can be useful is the identification of the wax a competitor is using in their coatings. Another application involves the identification of a substance that has built up on the metal tooling at a customer’s plant. Is it the wax? Is it the polymer? Or is it not the coating at all? Removing a few milligrams from the tool and running it in a DSC will usually provide the answer.

The final example involves a baseline shift which is difficult, if not impossible, to uncover using LTDSC. The total heat flow for an MTDSC run is shown in Figure 12. It appears that there is a $T_g$ at about 20°C. However, the event at 20°C had nothing to do with the polymer. For some reason the baseline shifted at about room temperature. That is, the symmetry of the cell changed at about room temperature. Regardless of the reason for this shift, a downward shift in baseline appears $T_g$-like when looking at the total heat flow. However, with MTDSC you will not be fooled because the amplitude of the modulation will not change during a baseline shift. Figure 13 shows the output signal from the cell versus the temperature of the sample side (averaged over a modulation) and its amplitude, which is simply the heat capacity. Here it is clear that the event at about room temperature is not a $T_g$, but rather a baseline shift because the amplitude of the output signal does not undergo a transition. The true $T_g$ is at about 45°C where the amplitude of the output signal increases significantly, indicating that the sample’s heat capacity has increased. That is, the amplitude of the thermal energy modulation...
of the furnace needed to produce a 1 °C modulation in the sample side temperature has increased.

2.6 Method Development

In MTDSC the temperature scan rate or linear underlying temperature rate can be set to zero. The technique of modulating around a fixed temperature and monitoring the output signal as a function of time has been called quasi-isothermal MTDSC. This technique can be used to elucidate the nature of crystallizations and glass transitions. Typical experimental conditions for an isothermal step are an amplitude of a 0.1 K and periods ranging from 30 to 100 s. The entire quasi-isothermal experiment will consist of a series of isothermal steps across the transition of interest that are perhaps 0.1–0.2 K apart. Typically, each isothermal experiment will run for 20 min with data accumulation over the last 10 min. In contrast with a continuous temperature scan which results in a continuous line representing heat capacity versus temperature, the results of a quasi-isothermal MTDSC experiment consist of a series of points each representing the heat capacity at (or around) a particular temperature. The advantage of a series of quasi-isothermal steps is that a steady state is achieved by simply waiting and there is no need to deconvolute the effect of the underlying linear temperature rate from the effect of the modulation because the underlying linear heating rate is zero.

Another novel development in MTDSC is the light-heating technique, developed by Saruyama. This technique allows higher modulation frequencies to be accessed by employing a light beam directed on the sample, which is attenuated by a polarizer rotating at a constant frequency. The intensity of the beam determines the modulation amplitude, and the angular frequency of the rotating polarizer determines the period of the modulation. The underlying heating rate is supplied by a conventional heating source, allowing access to high frequencies of modulation.

Still another, and perhaps the most technically impressive, development in this fertile field is the marriage of DSC and AFM into a technique called microthermal calorimetry. In this new technique the AFM tip is fitted with an ultraminiature temperature probe that acts as both the heat source and the detector. Obvious applications include the characterization of micromorphology, and detecting and identifying contaminants. The accessible frequencies with this technique are much higher than with normal MTDSC simply because the mass whose temperature is being modulated is much smaller. Indeed, varying the frequency of the modulation is a means of depth profiling from the surface.

3 DYNAMIC MECHANICAL ANALYSIS

3.1 History

The development of modern DMA began with the torsion pendulum. This instrument consists of a clamping mechanism that allows the sample to be deformed in the torsion mode (twisted). When the sample is released from the twisted state it recovers with a damped oscillation around its equilibrium position. The frequency of the oscillations can be related to the shear modulus of the sample and the damping of the oscillations (rate of decrease in amplitude) can be related to the loss modulus of the sample.

A torsion pendulum was used to study the mechanical properties of free films as early as 1966. The development of DMA has progressed significantly from the custom-made torsion pendula of the 1960s. Commercial instruments of the late 1990s have numerous deformation modes, precise temperature control, and a wide range of deformation frequencies. Along with the sophisticated hardware comes software with the ability to analyze, fit, and smooth the data.

3.2 Dynamic Mechanical Analysis Fundamentals

In general, DMA is a technique that is used to characterize the response of a material to a periodic perturbation as a function of frequency, temperature, or time. This periodic perturbation can consist of a constant oscillation amplitude at a fixed frequency or a free oscillation at the resonant frequency. The response includes both the elastic component, which is in phase with the perturbation, and a viscous component, which is out of phase with the perturbation.

To obtain quantitative results for the absolute value of the moduli from a DMA test, the sample must be uniform and its geometry well known. For this reason the DMA testing of coatings is usually qualitative because the two most widely used sample configurations – coated braid and free film – preclude precise knowledge of the sample geometry, the sample uniformity, or both. However, in this case qualitative does not imply inadequate. In many cases DMA testing of coatings involves a rank ordering of coatings rather than a determination of absolute moduli.

A couple of advantages that the DMA technique has over other thermal analysis techniques are the ability to detect lower-order transitions and the ability to simultaneously determine the viscous and elastic moduli of the material. The lower-order transitions, which have been attributed to side chain motions of the polymer, are related to the ability of the polymer to respond to fast deformations without exhibiting catastrophic failure. A polymer coating may be subject to such deformations in a precoat postform process, when
exposed to vibrations, or when subject to an impact from, say, a rock. The DMA is a useful instrument to employ when developing, for example, sound-absorbing coatings, impact resistant coatings, and coatings for a flexible substrate. Any exterior coating falls into the latter category due to the thermal expansion and contraction of the substrate with temperature and – in the case of wood substrates – relative humidity.

3.3 Sample Preparation

Basically there are two sample configurations used to test coatings in a DMA. One is a free film and the other is a supported coating. There are advantages and disadvantages to each method. A free film usually has a measurable thickness and the preparation of the film can usually be controlled to a greater degree. The drawbacks of using a free film are numerous. First, in most cases it is quite difficult, to obtain a free film that is representative of the film as prepared on the substrate. Removal of the film from the substrate often irreversibly stretches or damages it, whereas chemical removal of the substrate from the coating (for example, with acid) raises questions of the effect of the chemical on the coating. If a representative free film can be obtained, mounting it in the DMA presents a significant experimental challenge. If, somehow, a free film is removed from its substrate without changing it and is successfully mounted in the DMA, there still remains the question of film thickness. The percentage variation in thickness of a thin free film (1 cm by 4 cm by 0.0025 cm) will usually be greater than the percentage variation in a rectangular slab of a polymer (1 cm by 4 cm by 0.25 cm) prepared in a mold. This is due to incomplete leveling of the thin film. If a film is not uniform, the modulus calculated by the software from the force data will be lower than the true modulus of the polymer because the film was not deformed uniformly.

The second option is to provide a support for the film. The two basic methods of supporting a coating are with a flat, solid substrate and with a mesh or absorbent fiber. An example of the former type is a coating applied to a metal panel and an example of the second type is a coating-impregnated fiberglass mesh. A flat substrate still provides some information about the geometry of the film, and semiquantitative results can be obtained if the response from the substrate can be deconvoluted from the response from the coating.

A mesh can be used when the film or coating is too weak to support itself. This is the case when studying the cure or drying of a coating. Just prior to testing, a known amount of liquid coating (typically about 25 µL) is spread evenly across the mesh. The surface tension of the coating is sufficient to keep the liquid from dripping off the braid. During the cure or drying of the film the elastic modulus of the coating will increase, and this increase will be evident in the results.

3.4 Experimental Conditions

The difficulty in choosing the optimal experimental conditions has increased with the complexity of commercially available instruments. First, the operator has to choose the mode of deformation. The most common mode is the two-point bend whereby one end of the sample is held fixed and the other end is oscillated sinusoidally. Other modes include the three-point bend, shear, torsion, compression, and tension. After the mode of deformation is chosen, the operator must select the experimental conditions. These include the sample length, the amplitude of the deformation, the frequency or frequencies of the deformation, and the temperature protocol. If the sample has a relatively low modulus a shorter sample should be used, and if the sample has a high modulus a longer sample should be used. The amplitude of the deformation should be large enough to create a useful restoring force but not so large that it exceeds the linear response region. Consult the instrument manual for guidelines on setting experimental parameters for a given sample stiffness.

Ideally, a range of frequencies should be chosen. This will provide information regarding the relationship between both the elastic and loss moduli and the frequency of deformation. The temperature program may consist of a constant scan rate, a constant temperature or a combination of both. For example, the temperature program of a cure experiment may consist of a jump from room temperature to 400 °F, a 10 min isotherm at 400 °F, a jump to −100 °F, and finally a scan at 2 °C min⁻¹ from −100 °F to 400 °F.

3.5 Applications

The application of DMA to coatings can be divided into two main groups – consumer and industrial. Consumer coatings consist of paints, lacquers, etc. that are applied by the consumer and dried at ambient temperature. Most industrial coatings are subjected to a bake which accelerates drying and, in the case of a thermost, promotes a chemical reaction. DMA can be used either to characterize the final cured or dried film or to characterize the transition from a wet coating to a final film.

The first example involves the ranking of exterior paints for low-temperature film formation. That is, whether the films will dry completely at low temperatures. The temperature used in this study is a stretch target for exterior house paint application, namely 30 °F. Three paints were studied. The experimental protocol consisted of applying 25 µL of coating to a fiberglass braid and holding its temperature at 30 °F for 700 min. Following the 700 min isotherm, the temperature of the sample was
scanned from $-25^\circ\text{C}$ to $100^\circ\text{C}$. The storage modulus during these temperature scans is coplotted in Figure 14. If the paint is completely dry, the modulus should not increase with temperature. Any increase in elastic modulus with temperature is evidence of an incomplete dry. From the results of the scan we can conclude that the paint B has the best low-temperature film formation, paint C is second best, and paint A has the most incomplete film formation at low temperature as its elastic modulus increased significantly during the temperature scan.

The second example involves the determination of whether a higher-$T_g$ additive would adversely affect the flexibility of an exterior house paint. An exterior house paint must be soft enough to expand and contract with the outside of the house as the exterior temperature changes. However, it also must be hard enough to resist dirt pick-up when the wind blows dust and dirt against the house. Paint formulators often combine hard and soft polymers in the formula in an attempt to produce a paint with both sufficient flexibility and low dirt pick-up. In this example, the formulators were considering replacing one of the components with a higher-$T_g$ polymer, but were concerned that this would compromise the excellent flexibility of the product. To investigate this, the standard coating and the coating with the higher-$T_g$ component were dried on a fiberglass braid under identical conditions. A coplot of the flexural loss modulus, as determined during a temperature scan at a rate of $2^\circ\text{C} \text{ min}^{-1}$, is shown in Figure 15. It can be seen that the low temperature loss modulus is virtually unaffected by the addition of the higher-$T_g$ component. Only at about $50^\circ\text{C}$ does the difference between the coatings become evident. Clearly, the higher-$T_g$ component can be used in the formula without sacrificing the ability of the coating to respond to the contraction and expansion of the house with temperature.

3.6 Dynamic Mechanical Analysis Method Development

Recent developments of DMA have involved expanding the range of applied forces, increasing the range of allowable frequencies, increasing the temperature range over which experiments can be performed, and increasing the number of modes of deformation. That is, much of the recent development has involved engineering rather than science. Current instruments have the ability to oscillate samples at 200 Hz using forces of up to 18 N with a temperature range from $-150^\circ\text{C}$ to $600^\circ\text{C}$. With modern instrumentation, all of this can be accomplished with a strain resolution of about 1 nm.

With these engineering developments comes an increase in the capability and speed of the software used both to control the instrument and to analyze the data. Temperature programs can consist of rapid coolings or heatings and they can contain numerous temperature excursions as well as isotherms. Software permits extensive coplotting as well as advanced data handling and curve-fitting procedures.

4 THERMOMECHANICAL ANALYSIS

4.1 History

The precursor to the modern thermomechanical analyzer is simply a dilatometer that measures a sample’s dimensions as a function of temperature. In this way the sample’s
linear or volume expansion coefficient can be determined. With the widespread use of polymers in engineering applications, the need to monitor the sample's change in dimension as a function of time under a load at constant temperature (creep) became apparent. Further, the need to determine a material's response to either a tensile or compressive force as a function of temperature and time became necessary. These requirements were the driving force behind the development and commercialization of today's modern thermomechanical analyzers.

4.2 Thermomechanical Analysis Fundamentals

Conventionally, TMA involves the measurement of a linear dimension of a material as a function of temperature or time when the material is subject to a stress (either compressive or tensile). TMA is similar to DMA in that the instrument is monitoring the material's response to an applied force. However, the instrument-naming convention is such that instruments that perturb the sample with a force of constant magnitude are called TMAs, and instruments that perturb the sample with a force that varies sinusoidally are called DMAs. A typical TMA sample cell set-up to measure a sample under load is shown in Figure 16. The sample under investigation rests on a stage and a probe is brought down on top of the sample with a predetermined force. The measured parameter is the distance between the tip of the probe and the stage upon which the sample rests. If the sample expands, as it might when heated, the measured distance increases; if the sample contracts or softens, the measured distance will decrease. A modern instrument comes with a variety of probe tips. Sharp or hemispherical probes are used to measure softening points and large flat probes are used to measure coefficients of linear expansion. In the coatings laboratory, TMA is used primarily to determine softening points of coatings.

4.3 Sample Preparation

When attempting to measure the softening point of a coating there is no compelling reason to remove the coating from the substrate. Therefore, coatings are usually tested in situ. Of course, it is helpful if the substrate is flat and will lie flat on the instrument's stage. Frequently, the only sample preparation required to analyze a coating is to cut a piece of the coated substrate that is small enough to fit on the stage (typically about 1 cm across).

4.4 Experimental Conditions

The conditions chosen by the user are probe type, the force exerted on the sample by the probe, and the temperature program. For a penetration experiment, the probe tip should be relatively sharp, such as a hemisphere of small radius. The applied force should be sufficient to eliminate the noise in the distance measurement, but not so great as to cause premature damage to the coating. A typical value for the applied force when a hemispherical probe tip is used is 0.25 N, which is the force of gravity on a mass of about 25 g. Frequently, the temperature program consists of a simple linear scan through the temperature regime of interest. A typical scan rate is 5°C min⁻¹.

4.5 Applications

A wet decorative coating may be dry to the touch after only a few hours but it continues to develop physical properties for a couple of weeks after it is applied. To quantify this, a series of experiments were performed on a test coating after a series of ageing times.

The results, coplotted in Figure 17, show that the probe starts to penetrate significantly into the coating at roughly 50°C. At 7 days drying, the penetration is deep, being about 15 µm. After 14 days of drying, the maximum penetration depth is less than at 7 days, and after 28 days of drying the penetration depth into the coating is less than 5 µm. From these results we can conclude that the coating is still building integrity after a month of drying. By adding specifically designed ingredients the cure of the coating can be accelerated and the effect quantified with TMA.

4.6 Thermomechanical Analysis Method Development

A recent improvement in the software that controls the TMA instrument provides an option for the linear temperature scan through the regime of interest. This
MaxRes technique will lower the temperature rate in direct proportion with the rate at which the distance between the probe tip and the sample stage is changing. That is, the temperature rate will be decreased during softening and increased when the sample dimension is constant. Thus, the temperature rate through the transitions is relatively small and the temperature rate through steady-state regions is relatively large. This decreases the total time to run a series of experiments, while increasing the sensitivity in the temperature regimes of importance.

A significant advance in TMA is the capability to apply a dynamic load to the sample. That is, a force that changes, linearly or sinusoidally, with time. Dynamic load TMA will provide the user with a tool to rapidly map the softening rate profile of a coating for any temperature and applied pressure.

Another recent advancement in TMA involves the monitoring of the temperature of the sample in a manner that allows the characterization of thermal events that occur within the sample. That is, when the temperature of the sample deviates from the steady state, a thermal event is occurring within the sample. With such an instrument, simultaneous measurements of the displacement trace and the temperature difference trace can be plotted against temperature. Thus, changes in the modulus of the sample can be related to thermal events within the sample.

5 THERMOGRAVIMETRIC ANALYSIS

5.1 History
The concept that the mass of an object will change upon heating goes back at least 2000 years to when the Egyptians heated materials on a balance over a fire. The term thermobalance was coined by Honda in 1915 in his paper on the degradation of various oxides. The appearance of commercial thermobalances occurred in 1963.

5.2 Thermogravimetric Analysis Fundamentals
The TGA technique accurately measures the change in mass of a material as a function of temperature. The change in mass can be due to a number of phenomena, such as degradation, evaporation, oxidation, absorption, or desorption. Modern electrobalances used in quality TGAs are sensitive to a change in mass of 100 ng.

5.3 Sample Preparation
For most TGA experiments the sample preparation is very simple. All that is required is to isolate a representative piece of the material to be tested. Sample masses are typically tens of milligrams. Typically, the sample is placed in the center of a pan which is hanging from a microbalance. The pans are usually aluminum or platinum, the latter being required for high-temperature applications.

5.4 Experimental Conditions
There are a number of factors to be chosen to run a simple TGA experiment. First, there is the temperature rate and the range over which the temperature is scanned. The linear scan rate should be small enough to accurately assign a temperature or temperature range to the phenomenon of interest. If the sample has a low surface-to-volume ratio (as for a large single piece), the temperature rate should be decreased when attempting to characterize a bulk phenomenon. However, if the sample has a high surface-to-volume ratio (as with a fine powder), higher temperature rates can be used. Often, an unknown sample is run first with a high temperature rate for the purpose of discovering the temperature (or temperatures) at which the mass changes. Once these are known the temperature can be scanned slowly through the regions of interest. Of course, if the instrument is more than a simple TGA, there are other experimental parameters that must be chosen.

5.5 Applications
In coatings development, especially in coatings for food or beverage containers, it is important to know whether the coating will absorb certain gases that may affect the flavor of the contents. In this example, a polymer is tested for selected absorbance of carbon dioxide. Over the first
part of the experiment the polymer is exposed to high-purity nitrogen gas. After the mass of the sample has settled somewhat, the purge gas is switched to carbon dioxide. Following the apparent decrease in mass due to the buoyancy of the heavier carbon dioxide, there is a slow absorption of carbon dioxide into the polymer. Later in the experiment the purge gas is switched back to nitrogen. Here the desorption of carbon dioxide from the polymer can be monitored. The force on the balance is plotted against time in Figure 18. The jump in weight after the switch from carbon dioxide back to nitrogen is due to the greater density of the carbon dioxide. Various coatings and components thereof can be tested to qualitatively rank their relative permeability to carbon dioxide and the solubility of carbon dioxide within them.

A second example involves the detection of a contaminant in a coating. The contaminant is known to have a degradation temperature of about 530 °C, which is fortunately higher than the rest of the coating. The contaminant was present at a concentration of only a few parts per million. At this concentration its presence would be virtually impossible to detect by TGA. However, the liquid coating was placed in a centrifuge which increased the level of contaminant in the solids (if it was present) by a factor of roughly 1000. The concentrated sample was placed in the TGA and the temperature was scanned from room temperature to 600 °C at a rate of 10 °C per minute. The results are shown in Figure 19. The presence of the contaminant is revealed by the mass loss between 500 °C and 550 °C. The amount present in the original sample can be approximated by dividing the concentration of contaminant in the sample tested by the factor by which the sample was concentrated with the help of the centrifuge.

### 5.6 Method Development

There are many possibilities for the combination of a TGA with other analytical instruments. The addition of some thermocouples to a TGA provides simultaneous TGA and differential thermal analysis (DTA). That is, a differential thermal analyzer as well as a TGA. With this set-up the user is better able to characterize various weight losses. For example, even though both evaporation and degradation result in a loss of sample mass, an evaporation is endothermic whereas a degradation is exothermic. The difference in the character of the mass loss will be evident with the DTA.

By adding a Fourier transform infrared or a mass spectrometer to the purge gas output from the sample cell, the gas coming off the sample can be analyzed for chemical composition. This is called EVA (evolved gas analysis).

Another advance in basic TGA is controlled-rate thermogravimetric analysis (CRTGA). With this method the temperature rate is controlled in such a way as to make the mass loss constant. In regions where the sample is virtually steady state, the temperature rate will be high and in regions of degradation or evaporation the temperature rate will be slowed considerably. This has the effect of maximizing the sensitivity of the weight loss in regions of interest.

The final development in basic TGA is the addition of a modulated temperature signal to the linear temperature rate – MTGA. By subjecting the sample to a temperature modulation, the rate of weight loss is measured at a wide range of temperature rates rather than the single temperature rate used in ordinary TGA. This allows a more precise calculation of activation energies and pre-exponential factors.
6 SUMMARY

A well-equipped thermal analysis laboratory has the potential to provide significant guidance to a coatings research and development team. However, to fully capitalize on the capability of the equipment, the users must possess the ability to skillfully prepare the samples, efficiently design an experiment, and properly interpret the results.

Environmental Trace Species Monitoring: Introduction

Markus W. Sigrist  
ETH Zurich, Zurich, Switzerland

Today, air pollution is an issue of great concern worldwide. This is manifested by tremendous scientific and technological effort in various fields as well as by the activities of many international organizations such as the Intergovernmental Panel on Climatic Change (IPCC) and the United Nations Conference on Environment and Development (UNCED). The first conference held in Rio de Janeiro, Brazil, was succeeded by various conventions such as the Framework Convention on Climatic Change (UNFCCC) that resulted in the Kyoto protocol in 1997. Finally, the Nobel Prize in Chemistry in 1995 was awarded for the first time to scientists researching in atmospheric chemistry (Paul Crutzen, Mario Molina and Sherwood Roland).

The main components of the air we breathe are nitrogen, oxygen, argon, carbon dioxide and water vapor which account for 99.9998% of its density. It is recognized, however, that the remaining trace concentrations of atmospheric species have a great impact in diverse areas. One cubic meter of air contains 1.1 mg of methane, 60–250 µg of carbon monoxide, 50 µg of hydrogen, 30–200 µg of ozone, 0.6 mg of nitrous oxide, 8–170 µg of nitric oxides, 0.2–100 µg of sulfur dioxide and 1–100 µg of particulate matter. The given values obviously vary with location and altitude. Both trace gases and aerosols contribute to well-known phenomena such as global climatic change, photochemical smog formation, acid rain, stratospheric ozone depletion, and forest decline (Figure 1). Ever increasing concentrations of numerous trace species during the 20th century, arising from increasing population, industrialization, road and air traffic, have contributed to the negative consequences that have become a matter of public concern. Another aspect is the danger of catastrophic emissions of toxic substances into the environment, most dramatically manifested by recent past disasters, such as in Seveso (Italy) in 1976, in Bhopal (India) in 1984, in Tschernobyl (Ukraine) in 1986, or in Schweizerhalle (Switzerland) in 1986.

The role of atmospheric aerosols which contribute only about $10^{-9} – 10^{-7}$ to the mass of the air is manifold. An aerosol represents a two-to-three phase system consisting of liquid and/or solid particles and a gaseous medium in which the particles are suspended. Aerosols provide reaction sites for pollutant gases, influence cloud formation and modify precipitation by functioning as condensation nuclei, and act as carriers for pollutant transport. The aerosol particles have various origins including both natural (e.g. volcanoes) and man-made processes. Globally, the natural aerosols dominate but in urban areas the anthropogenic aerosols are more important. As the tropospheric aerosols lifetime is about 1 week, atmospheric aerosols are widely distributed and they can have a large spatial and temporal variability.

Today, there are regulations in many countries to govern the maximum concentrations of selected gaseous species at the workplace, emission limits for sources of pollution, or concentration standards for the open atmosphere. Furthermore, there exist lists of hazardous air pollutants (HAPs) like the one issued by the US Environmental Protection Agency (EPA). Ambient air quality standards for fine airborne particles, such as those emitted by Diesel engines, have been introduced according to their size and concentration. As example, the PM$_{10}$ and PM$_{2.5}$ values for particulate matter include 24-hour and annual average standards on the mass concentration for particles with aerodynamic diameters below 10 µm and below 2.5 µm, respectively. These standards are considered as an important measure for health hazards. They are often not met in urban, suburban or even rural areas. A detailed knowledge of source contributions to PM$_{10}$ and PM$_{2.5}$ values is still lacking, despite their significance for the development of reduction strategies.

Both the global impact of trace species and the examples of local hazardous emissions demonstrate the need for versatile analytical techniques and for remediation schemes. Measurements of ambient air compounds include several diverse fields: urban (traffic emissions); industrial (petrochemical industry, combustion sites, waste incinerators, semiconductor manufacturing process control); rural (background concentrations, greenhouses, fruit storage); medical diagnostics (exhaled breath gas monitoring); and spacecraft habitat air quality monitoring.

The large number of trace species, their distribution and diversity pose a great challenge with regard to the development, implementation and application of

---

**Figure 1** Illustration of the significance of atmospheric trace species for environmental issues.
such methods. Different kinds of devices are used for aerosol detection including simple instruments for light transmission measurements, or porous filters to collect material for determining the mass concentration, as well as sophisticated sensors to characterize the particle size distribution and chemical composition.\(^{(1,2)}\)

Ideal analytical tools for trace gas sensing have to meet several requirements, such as multicomponent capability, high sensitivity and selectivity, high accuracy and precision, large dynamic range, good temporal resolution, ease of use, versatility, reliability and robustness. However, most techniques cannot simultaneously fulfill all requirements so that one has to compromise between the most important features for a given analytical application or task. In the following the desired properties are briefly discussed individually.

- **Multicomponent capability** This is often important because in most situations the trace species, such as a gas to be detected, is not isolated but contained in a mixture. Hence, it is desirable to know additional compounds present in the mixture that may cause harm to the environment. Of course, this could be achieved by measurements with a variety of different instrumentation but at the expense of time, easiness, cost, etc.

- **Sensitivity** Usually, concentrations are given in units of ppm (\(10^{-6}\), corresponding to micromole per mole), or ppb (\(10^{-9}\), nanomole per mole), or else in milligrams per cubic meter or in micrograms per cubic meter volume of air mass. It is evident that instruments with extremely high sensitivity are required for measurements in rural areas, for instance in the monitoring of background concentrations of trace compounds.

- **Selectivity or specificity** This represents a crucial aspect in cases where an individual species is to be monitored in a mixture of various compounds. This scenario is very often encountered and is thus related to the multicomponent capability. It permits quantitative analysis or at least selective monitoring of specific compounds in mixtures. However, there are also situations where it is sufficient to quantify the concentration of just a group of compounds. An example is the total hydrocarbon concentration monitored in regular exhaust checks in a car garage.

- **Accuracy and precision** These two scientific terms are often confused. Accuracy is a measure on how close the measurement value is to the true value, whereas precision is a measure of the range of values obtained from repeated measurements on samples with identical concentrations. As a result accuracy is an important criterion when testing the observance of regulatory standards or when comparing different measurement schemes, whereas precision is the important feature when recording the trend of a species concentration at the same location. This property is connected to the sensitivity—the closer the measured concentration approaches the detection limit, the smaller the precision of the measurement.

- **Dynamic range** A large dynamic range allows to sense pollutants in rather different environments with one and the same instrumentation. At the source of emission, such as at a gas leak, concentrations can be as high as in the percent range, whereas far away from a source in a rural area the same pollutant can be present in concentrations at ppb or even ppt levels.

- **Temporal resolution** This is important when concentration fluctuations on short timescales of, say, minutes, are to be expected, when the interest lies on flux measurements or on the temporal evolution of species, as after a gas leakage. In these situations on-line and real-time sensing is often required. However, time resolution is of minor concern for cases like the surveillance of the ambient atmospheric CO\(_2\) concentration.

- **Ease of use** This is desirable in several respects, such as easy implementation and preferentially unattended automated operation of the measurement system, preferentially room-temperature operation, easy maintenance and tolerable costs.

- **Versatility, reliability and robustness** These are all important for applications at all various locations outside the laboratory such as in cold, hot, humid, noisy environments in the field, in airplanes, or even in spacecraft or satellites.

Other features not mentioned here can be important for selecting one or another technique for a certain monitoring task (e.g. requirements for sample preparation, size, weight, etc.).

In the past, numerous techniques ranging from chemiluminescence to gas chromatography have been developed and successfully applied to trace gas monitoring.\(^{(3)}\) Some of these schemes have become standard methods and are widely used on a routine basis. However, several requirements cannot be fulfilled by conventional techniques. This is particularly true for the number of species that can be detected with a single-measurement device, i.e. the multicomponent capability, and problems related to sample preparation. In recent times, optical techniques have attracted considerable interest.\(^{(4)}\) They offer some unique features that are relevant for the monitoring of atmospheric constituents. A key issue is the contact-free measurement of the sample, the lack of any preconcentration, or any kind of pretreatment of the sample. Finally,
as only schemes they offer the possibility of remote three-dimensional sensing in the open atmosphere from the ground or from space.\textsuperscript{(1, 5, 6)}

Today, there is a great variety of optical schemes. They can be separated into those that use conventional light sources such as Xe lamps and the laser-based devices (Figure 2). The latter essentially rely on lasers that are tunable in appropriate wavelength ranges. The advantage of lasers is their extremely high spectral brightness, which is not achievable with conventional sources combined with filters or gratings. This characteristic laser property forms the basis for a high detection sensitivity and selectivity. However, conventional light sources often offer a larger tuning range which can compensate for the lack in spectral brightness and which is also important when a multicomponent capability is required. Furthermore, broadly tunable lasers are still often complex and expensive devices, which can hinder their wide distribution. However, this situation may change in the future with the development of compact diode laser-based systems.

As Figure 2 implies, the basis of all optical schemes is some kind of interaction process between the radiation and the air mass (gases and aerosols) to be monitored. The essential processes involved are absorption, Rayleigh and Raman scattering, fluorescence, and combinations thereof. Hence, these methods are based on spectroscopic properties of the species under study. Apart from these techniques there are further optical schemes, such as fiberoptic sensing, laser mass spectrometry and laser-induced breakdown spectroscopy (LIBS), that use other (nonspectroscopic) effects for the production of the relevant monitoring signal.

Finally, it should be emphasized that there is no single technique that meets all the requirements mentioned above. However, there is a large variety of instruments available (sometimes with complementary performance) from which one can select a device that can be tailored to the needs of the application.

This section of the Encyclopedia describes the various techniques available and their application to the sensing of trace species in different environments. Emphasis is placed on optical schemes and trace gases. The selection of articles has been made on the basis of the current distribution, significance and impact of the method. A broad coverage of application areas has also been taken into account. The techniques selected are either already well established or else represent very promising methods with a great potential in various application fields. Although lasers have had a great impact in diverse areas including environmental sensing, non-laser-based spectroscopic systems also carry great potential and the presently most promising schemes are treated here as well. The applied wavelengths span from the ultraviolet to the infrared (IR) region. New developments can be expected from such techniques mainly in combination with future laser developments, such as quantum cascade lasers, and other technological achievements. The individual articles are reasonably self-contained. They are written by authors who were selected for their expertise in the field and their own original contributions.

A comprehensive presentation is given of the fundamentals and of the state-of-the-art, illustrated by application examples. Although the list of articles is by no means complete, it should still give an impression on optical methods, their performance, and their limitations in trace species monitoring.

The first article, by L. Stefanutti and S. Borrmann, National Research Council, Florence (Italy), is on Airborne Instrumentation for Aerosol Measurements. This includes remote sensing instruments, direct reading in situ methods, and sampling devices followed by sophisticated laboratory analyses. The detection limits and ranges, the reliability and areas of applications as well as the different platforms used are addressed.

U. Platt, University of Heidelberg (Germany), presents the article Differential Optical Absorption Spectroscopy, Air Monitoring by. After a discussion of the fundamentals of molecular scattering and absorption, the author outlines the different modes of differential optical absorption spectroscopy (DOAS) operation followed by a description of practical designs and characterization of DOAS systems, evaluation techniques for DOAS spectra and concludes with a discussion of some applications.

M. Tacke et al., Fraunhofer Institut fuer Physikalische Messtechnik, Freiburg (Germany), gives an overview on Laser Absorption Spectroscopy, Air Monitoring by Tunable Mid-infrared Diode. The lasers employed are cryogenically cooled lead salt diode lasers. The basics of this technique are discussed and various
examples of applications in air monitoring are presented, including ground and airborne measurements, rocket experiments, and exhaust analyses. Finally, a comparison with alternative schemes is given.

F.K. Tittel, Rice University, Houston (USA), and K.P. Petrov, Gemfire Corporation, Palo Alto (USA), discuss a different approach to Diode Laser Spectroscopic Monitoring of Trace Gases by employing room-temperature difference frequency mixing in nonlinear optical materials to access the important mid-IR spectral region. After discussing some fundamentals of gas phase spectroscopy in general, they compare the merits of different tunable laser sources followed by a discussion of the available techniques for measuring small gas concentrations. They conclude with a presentation of several examples of trace gas sensors based on this novel diode laser technology.

D. Griffith, University of Wollongong (Australia), describes Fourier Transform Infrared Spectrometry in Atmospheric and Trace Gas Analysis. He includes both open path and closed long path measurements in specially designed gas cells. Remote sensing is presented as ground-based solar absorption Fourier transform infrared (FTIR) spectroscopy. IR emission studies on stack plumes, volcanoes and hot sources are examples of applications of this technique.

The potential of Photoacoustic Spectroscopy in Trace Gas Monitoring is treated by F.J.M. Harren, University of Nijmegen (The Netherlands). The author gives a history of this effect which was discovered in 1880 by A.G. Bell, followed by a detailed discussion of the devices and equipment used nowadays. Possible limitations, detection limits and selectivity issues are also presented. The performance is illustrated with many examples including stack gas and car exhausts emissions, as well as ambient air monitoring. The wide scope is manifested by biological and medical applications. These include studies on postharvest research, plant physiology, microbiology, entomology, molecular biology, soil science and noninvasive human breath analysis.

Matrix Isolation Spectroscopy in Atmospheric Chemistry as a further quantitative analytical tool is outlined by K.S. Viswanathan, K. Sankaran and K. Sundararajan, Indira Gandhi Centre for Atomic Research, Kalpakkam (India). The authors highlight the advantages of this technique particularly for applications in atmospheric chemistry, such as quantitative estimates of atmospheric trace gases and reactive species. The evaluation of the appropriate matrix, the detection system and the sampling methods are presented as well as the use of the technique for studying reactions of atmospheric species such as NO$_x$, halomethanes, ozone, and OH radicals.

The LIDAR (light detection and ranging) scheme is presented in two contributions differentiating between ultraviolet-to-visible (UV/VIS) LIDAR and IR LIDAR. Both chapters demonstrate how lasers can be employed to detect trace species at a distance. The Ultraviolet/Visible Light Detection and Ranging Applications in Air Monitoring article, written by J.P. Wolf, University of Lyon (France) describes the DIAL (differential absorption LIDAR) principle and gives examples of DIAL systems. On the one hand, the mapping of gaseous pollutants is discussed for traffic-induced NO$_x$ distribution in cities, chemical dynamics of ozone production, industrial SO$_2$ plume studies, and diffuse emissions of VOCs (volatile organic compounds). On the other hand, LIDAR systems are employed for the measurement of urban aerosols, the detection of soot, or the multispectral monitoring of stratospheric aerosols active in the ozone layer depletion. The article also includes the validation of numerical models, comparisons with other techniques, and a discussion on new standards.

The Infrared LIDAR Applications in Atmospheric Monitoring is addressed by B.J. Orr, Macquarie University, Sydney (Australia) and starts with a survey on optical and atmospheric processes like the forms of light scattering, atmospheric transmission and spectroscopic signature of common atmospheric molecular species. These play a crucial role for the choice of laser wavelength, bandwidth, sensitivity, etc. An overview of the different types of LIDAR schemes including IR/DIAL and Raman systems follows, with a detailed presentation of coherent IR light sources appropriate for LIDAR sensors. Finally, illustrative examples of air monitoring are given and perspectives and future developments outlined.

Although fiberoptic sensors are commonly employed for sensing the parameters temperature, pressure, or pH values, there is an increasing interest in their application to gas analysis. The article on Optical Gas Sensors in Analytical Chemistry: Applications, Trends and General Comments by G. Gauglitz, University of Tuebingen (Germany), discusses the basics of these sensors with emphasis on planar waveguides. Applications are illustrated by some representative examples.

U. Boesl et al., Technical University in Munich (Germany), present the technique of Laser Mass Spectrometry in Trace Analysis. The main characteristics of the method are outlined including its development. The applications discussed comprise exhaust emissions from combustion engines (traces of aromatic compounds behind the catalytic converter at fast changes of engine conditions and control of oil traces in the exhaust) and from incinerators (on-line measurements of polycyclic aromatic compounds, isomer-selective analysis of polychlorinated aromatics). An example of great current interest concerns the possible realization of a fast dioxin analysis. Furthermore, the on-line monitoring of volatiles in the headspace of food products and during
food processing is discussed. Future developments concern calibration standards and the highly selective trace analysis of organic compounds in solid samples.

Three articles focus on specific applications rather than on the technique as such, namely on explosives detection, combustion diagnostics, and elemental analysis.

J.P. Singh and D.L. Monts, Mississippi State University (USA), present Laser- and Optical-based Techniques for the Detection of Explosives. These include IR, Raman, UV/VIS, laser-induced fluorescence, as well as mass and ion mobility spectrometries and chromatography. The authors address solid, liquid and gas-phase samples, and focus on water and soil in their discussion of environmental applications.

J. Wolfrum et al., University of Heidelberg (Germany), discuss Laser-based Combustion Diagnostics which include the linear techniques of absorption spectroscopy, laser-induced fluorescence and incandescence, Rayleigh and Raman scattering, as well as nonlinear techniques such as coherent anti-Stokes Raman scattering, degenerate four-wave mixing, polarization spectroscopy, sum frequency mixing and resonance-enhanced multiphoton ionization. The applications comprise diagnostics of laminar and turbulent flames, engine combustion, and coal and waste combustion.

In their second contribution, J.P. Singh and D.L. Monts, Mississippi State University (USA), address Laser-induced Breakdown Spectroscopy, Elemental Analysis. After a presentation of the technique and some fundamental studies, they focus on some examples of environmental applications, including molten metal, glass, soil, paint, air sampling filters, and radioactive species. The performance of LIBS with regard to accuracy and precision, sample preparation, sampling rate and detection limits is compared with competing techniques.

R. Hirschberger, Institut für Spektrochemie und Angewandte Spektroskopie (ISAS), Dortmund (Germany), focuses on Automotive Emissions Analysis with Spectroscopic Techniques. After a discussion of traditional techniques such as nondispersive IR and UV or chemiluminescence systems the author discusses more recent IR techniques based on FTIR and diode-laser systems with applications for on-line measurement and analysis of hydrocarbons. Linear and nonlinear Raman techniques are also presented, with applications for on-line and in situ measurements of hydrocarbons, hydrogen, oxygen, and nitrogen. The different methods are compared on the bases of handling, sensitivity, robustness, and costs. It is mentioned that most of these modern optical techniques are still laboratory research systems and have not yet been validated for field use.

Additional analytical methods for the trace analysis of air, not treated in this section, are presented in related sections of this Encyclopedia: Field Portable and Transportable Air and Vapor Measurement, Industrial Hygiene, Chemical Warfare Analyses, Environment (Water and Waste), Atomic Spectroscopy, Gas Chromatography, and X-Ray Spectrometry.

It should also be emphasized that the development and implementation of novel and improved instrumentation is an active field, so that devices with ever higher performance are regularly becoming available. It is thus hoped that this section may stimulate further research interest in the field of trace species characterization, analysis, and monitoring. Although detection schemes per se cannot solve the challenging problems associated with air pollution, they can nevertheless provide a solid basis toward a sustainable improvement of the environment.

ACKNOWLEDGMENTS

As editor of this section I wish to thank all the authors for the overviews of their specialties, which point out the advantages and drawbacks of the numerous techniques available and which demonstrate the state-of-the-art performance by illustrative applications. I acknowledge their cooperation in following the guidelines provided, thus ensuring a useful and comprehensive section with little overlap between chapters. I am also indebted to the editor-in-chief, R.A. Meyers, and the managing editor, A. Holyoake of J. Wiley & Sons, Inc., for their initiative, helpful suggestions, critical comments, and (last but not least) for their understanding and patience with late manuscripts.

1 Introduction

Solid-, liquid- and mixed-phase aerosol particles are present in our atmosphere. Their characteristics and distribution are highly variable and change spatially and temporally with altitude. Aerosols play a fundamental role as nuclei for haze, cloud and hydrometeor formation, as well as in meteorology and atmospheric chemistry, and have great influence on the atmosphere’s radiative budget. Therefore it is important to study the fundamental mechanisms involving particles and monitor changes related to the atmospheric aerosol. Various aerosol properties can be measured by means of satellites, airborne instrumentation, ground-based techniques and analytical methods in the laboratory. Ground-based in situ instruments measure physical and chemical properties of the aerosol on specific locations and constitute point measurements conducted usually for extended periods.

Remote sensing methods measure some optical properties of the aerosol and are capable of scanning a specific (often large) volume of air in the vicinity of the station. Similarly, satellite-based remote sensing instruments observe significant portions of the global atmosphere detecting large scale and coarsely resolved distributions of aerosols and clouds.

In order to obtain specific physical and chemical aerosol data, sometimes down to the scale of a single particle, airborne techniques have been developed to be deployed on aircraft or balloons utilizing passive and active remote sensing methods, as well as in situ techniques. Unlike aircraft, balloons are susceptible to uncontrolled wind drifts, but capable of reaching much higher altitudes.

The atmospheric region covered by airborne instrumentation extends from the planetary boundary layer (PBL) (from the ground to approximately 2 km) through the free troposphere (up to 17 km depending on geographical latitude and season) well into the stratosphere (from the tropopause up to 50 km).

In this article the different types of airborne instrument are discussed considering their detection limits and ranges, their reliability and range of applications. Also the different platforms available for airborne aerosol instrumentation and payload configurations are briefly described.

2 THE ATMOSPHERIC AEROSOL

2.1 Atmospheric Aerosols and Clouds

Aerosols are a natural constituent of the Earth’s atmosphere and their origin is mostly natural, although lately the anthropogenic contribution is increasing. The total
mass of natural aerosols was evaluated to be four times larger than the one due to human activity in 1968, and by the year 2000 the anthropogenic component is estimated to double.\(^\text{1,2}\) An aerosol is defined as a stable suspension of particles, liquid or solid, in a carrier gas like atmospheric air. Therefore dust, haze, smoke, smog, fog, mist, and clouds can be considered to be specific aerosol types. Atmospheric clouds are volumes of supersaturated air containing hydrometeors which are microscopic objects (e.g. aerosol particles, cloud droplets, ice and snow crystals) as well as macroscopic objects (snowflakes, graupel grains, raindrops, and hailstones). The individual particles have sizes with radii ranging from 0.001 \(\mu\)m to several hundreds of micrometers, or even centimeters as in the case of hailstones. According to Junge\(^\text{3}\) a first classification can be made based on particle size. The particles with diameters below 0.1 \(\mu\)m are named “Aitken particles”, those with sizes between 0.1–1 \(\mu\)m are “large particles”, and those larger than 1 \(\mu\)m are called “giant” particles.\(^\text{11}\) The aerosols may also be classified according to their origin into marine, continental, rural, remote, background, and urban aerosol, where each category has different characteristics like chemical composition, size distribution, shapes and so on. Aitken nuclei, i.e. the smallest atmospheric aerosol particles, are naturally produced from supersaturated vapors by a process called gas-to-particle conversion (GPC), often in connection with photochemical reactions between gas phase constituents. Anthropogenic activities like combustion and industrial processes increasingly lead to the release of aerosol particles, or precursor gases from which aerosol particles are formed, into the atmosphere. Large aerosol particles can be produced by combustion processes and other anthropogenic or natural processes (e.g. the coagulation of smaller Aitken nuclei). Natural sources for giant particles are bulk-to-particle conversion (BPC) processes like sea-salt aerosol production, or desert dust mobilization, and human activity contributes, for example through emission from industries, mining, biomass- and woodburning, and agricultural dust generation.

Figures graphically displaying the volume distribution of an atmospheric aerosol as function of particle size can exhibit up to three peaks (modes).\(^\text{11}\) These peaks are termed as “nuclei mode”, “accumulation mode”, and “coarse mode”. The nuclei mode consists of the primary particles formed by condensation of gases and vapors. Coagulation of such small particles, GPC and condensation of vapors onto existing small particles create the accumulation mode, and the particles contained in the coarse mode are predominantly generated by BPC. Typical modal particle sizes are diameters of 0.02 \(\mu\)m for the nuclei mode, and 0.2 \(\mu\)m and 5 \(\mu\)m for the accumulation and coarse modes, respectively. These sizes depend on sampling time and location of the atmospheric aerosol under consideration, and not necessarily all modes are present in a given sample. Although this “three-mode concept” is useful for theoretical and experimental studies, it has to be considered as a conceptual model because real atmospheric measurements may exhibit very different features.

Methods for aerosol measurement apply either physical or chemical principles. The number density of particles in the air for given sizes can be determined by using physical techniques. The thermodynamic phase of the particles, total mass concentration, total particulate surface area, total volume, and various optical properties can also be measured. On the other hand different chemical analyses are adopted in order to determine particle composition, density, and reactivity. Since the shapes of individual aerosol particles may be very complex and highly variable, the analysis of size-dependent parameters requires the introduction of an equivalent particle size diameter. This is defined as the diameter of a spherical particle which has the same physical properties (e.g. volume, cross-section for optical scattering) as the aspherical particle under investigation.

Because the particle size range encountered in the atmosphere spans as much as five orders of magnitude (or even seven if unstable aerosol populations like rain drops, snow flakes, and graupel grains are included), different techniques or even different physical principles have to be adopted in order to measure the aerosol property of interest. This cannot be achieved with a single instrument. For example, the sizes of small particles can be measured by detecting their mechanical or electrical mobility, while optical methods are employed for sizes above 0.3 \(\mu\)m up to roughly 100 \(\mu\)m.\(^\text{14}\) For the sampling of particles above approximately 0.1 \(\mu\)m, with the option of subsequent chemical analyses, techniques based on impacting particles on surfaces are suitable. Physical and chemical analyses on particle samples are performed by means of electron microscopy, X-ray fluorescence (XRF), atomic absorption spectrometry (AA), emission spectrometry (ES), infrared (IR) spectroscopy, anodic stripping voltammetry (ASV), electron spectroscopy for chemical analysis (ESCA), ion chromatography, laser microprobe mass spectrometry (LMMS), proton (or particle)-induced X-ray emission (PIXE), neutron activation (NA), among a variety of other methods.\(^\text{4,5}\)

The analysis of the vertical distribution of the physical and chemical aerosol properties is fundamental in the study of aerosol and cloud effects on the natural and anthropogenically disturbed environment.

For aerosol and cloud-related research, airborne platforms (like airplanes and balloons) are commonly utilized where platform type and instrumentation have to be
carefully selected depending on the specific scientific goals. The part of the atmosphere which is accessible to aircraft or balloons is structured in different layers with the PBL (from the ground up to approximately 1–2 km), the free troposphere (from the top of the boundary layer up to the local tropopause), and the stratosphere.

The characteristics and distribution of atmospheric aerosols are highly variable, changing spatially, temporally, and with altitude. The aerosol in the lower troposphere is particularly inhomogeneously distributed where large aerosol loads are found near the source regions (e.g. deserts) and during times of “outbreak events”. The measured particle size distributions can exhibit nuclei, accumulation, and coarse modes, where most of the time not all modes are simultaneously present in a particular size distribution measurement. Mathematically these distributions are described by a log−normal function, and such multimodal distributions are used as models characterizing most of the atmospheric aerosol types. The particle number concentration decreases with increasing particle size and Aitken particles dominate the total number of particles in an air sample. On the other hand their contribution to the total aerosol volume is small, while the largest contribution comes from the large and giant particles.

For particles with sizes ranging from a few nanometers up to tens of micrometers typical number concentrations can be coarsely specified, for example at the (continental) ground level total concentrations are near $1.4 \times 10^4$ cm$^{-3}$ particles with values decreasing towards $6 \times 10^2$ cm$^{-3}$ in remote locations. The total concentration in large cities is as high as $10^5$ cm$^{-3}$ particles, in small towns values around $3 \times 10^4$ cm$^{-3}$ are detected, while over the oceans, far from coastlines, $5 \times 10^2$ cm$^{-3}$ can be found. In clean Arctic environs measurements show total particle concentrations near $50$ cm$^{-3}$, in the remote Antarctic continent concentrations can be even lower. As with the atmospheric air density profile, the particle number concentration (in number of particles per cubic centimeter of air) shows an exponential decay for the lowest 6 km of the atmosphere. Above this level a background tropospheric aerosol is observed with values around 200–300 particles per cm$^3$ in the Aitken mode. Above the tropopause the total number concentration decreases again to a minimum below 1–10 cm$^{-3}$ particles which remains constant to altitudes around 30 km.

In the case of the large particles (i.e. those with sizes between 0.1–1.0μm) the total concentration decreases with altitude up to a minimum around 0.01–0.02 particles per cm$^3$ in the upper troposphere. In the stratosphere the values increase and a maximum around 0.1–1 particles per cm$^3$ is reached at altitudes between 17 km (in the polar regions) and 25 km (equatorial region) depending on geographical latitude, corresponding to up to $1.5 \times 10^{-7}$ μg cm$^{-3}$. Above this maximum the concentrations decrease again. This stratospheric aerosol layer of binary sulfuric acid solution droplets is named the Junge layer and the altitude of its maximum also varies with latitude. Aerosols play a fundamental role as nuclei for haze, fog, cloud, and hydrometeor formation. If the particles are solid they offer a surface on which trace gases can undergo chemical reactions. If they are liquid they absorb gases which can react inside the solution droplets, thus forming and subsequently releasing new compounds into the atmosphere. This chemical role is very important especially in the case of polluted air, both in the lower troposphere and in the stratosphere as it is, for instance, for stratospheric ozone chemistry and the acid rain phenomenon in the troposphere. Furthermore cloud and aerosols have great influence on the atmosphere’s radiative budget. Figure 1 from Intergovernmental Panel for Climate Change (IPCC) demonstrates this by displaying the global mean radiative forcing (also referred to as “greenhouse forcing”) for various radiatively important atmospheric trace substances, as well as the aerosol. These estimations include the changes (increases) in atmospheric concentrations of the displayed radiatively active compounds between the preindustrial era and 1992. Estimations of the change in forcing originating from variations in solar energy flux are indicated at the right side of the figure. The first bar indicates the contributions of four gases to the direct greenhouse effect. The indirect effects of the increase in tropospheric ozone and the decrease in stratospheric ozone on the greenhouse forcing is displayed by the next two bars. The following set of three bars pertains to the direct effect (see below) of the tropospheric aerosol. The single standing error bar following to the right represents the indirect effect on the aerosol of changing the cloud properties (see also below). This quantity is so uncertain that not even a mean value can be specified in the form of a bar as is possible for the other quantities in the figure. Of particular note are the error bars and indications of the confidence placed into these estimations which are given. These show large uncertainties for the role of the direct and indirect effects of the tropospheric aerosol. Here direct effects refer to the reflectance and extinction of radiation by the aerosols through scattering and absorption, whereas indirect aerosol-related effects are the modification of the formation and lifetime of clouds, the global and regional cloud coverage, as well as changes in the cloud optical properties. Therefore it is important to study the fundamental mechanisms involving particles and monitor changes related to the atmospheric aerosol and its effects.
Atmospheric aerosols and clouds are closely related, because each cloud droplet, ice crystal, and precipitation element in tropospheric clouds originates on an a priori existing aerosol particle. The levels of saturation with water vapor are never high enough in the atmosphere to allow for homogeneous homomolecular nucleation, i.e. the creation of liquid-phase water droplets directly from water vapor. Cloud droplets always form via heterogeneous nucleation on already existing aerosol particles. If the Earth’s atmosphere were free of aerosol particles, clouds and precipitation could not form. (As an exception, homogeneous heteromolecular condensation is possible in the atmosphere, as for example for the co-condensation of sulfuric acid and water vapor in the stratosphere.) Radiatively clouds influence the albedo of the planet, and chemically the cloud droplets act as little reactors influencing the chemical composition of the surrounding air. The distribution of the clouds, their optical, properties, as well as the chemistry associated with them are issues of primary importance in the understanding of climatic changes.

2.2 Tropospheric Aerosols

2.2.1 Planetary Boundary Layer

The largest part of the tropospheric aerosol is contained inside the PBL, where the majority of energy exchanges between the Earth’s surface and the atmosphere occur. Also most of the aerosol generating BPC and anthropogenic processes take place there. The global rate of aerosol production is estimated to be of the order of 2000 Tg per year, 15% of which are attributed to anthropogenic sources. One-fifth of these 15% is believed to originate from direct anthropogenic emissions, which implies that 80% of the anthropogenic contribution derives from GPC. The natural contribution to the global aerosol generation rate is 60% on account of direct emissions, while 40% are due to GPC. Urban aerosols are essentially anthropogenic and derive from combustion of fossil fuels, industrial and chemical production, as well as GPC and BPC. For example photochemical and sulfurous smog are typical phenomena connected with human activity in cities. In the vicinity of the ground the aerosol
content of the air is rarely less than 1 µg of particulate matter per cm³ of air. In cities values above 100 µg per m³ are measured, and in sandstorms aerosol loads of as much as 30,000 µg per m³ can occur. In general, if the measured mass concentrations of the aerosol are compared with those of the other atmospheric trace gases, then one finds that the contribution of the aerosol is equivalent to that of a trace gas in the ppbv (parts per billion by volume) range.

2.2.2 Free Troposphere

The free troposphere has less aerosols than the PBL. The largest part of the total atmospheric water vapor resides in the troposphere and the free troposphere is the location where clouds are found and the majority of meteorological events occur. Sand storms in desert areas produce clouds of dust and mobilize submicrometer-sized particles (silicates), which then can be transported in the free troposphere over distances of several thousand kilometers. Similarly forest fires cause the transport of smoke and soot over long distances. Aircraft exhaust emissions are sources of tropospheric and lower stratospheric aerosols, the concentrations, characteristics and effects of which are largely unknown and are the subject of intense research. The generation of water vapor from the aircraft exhaust also influences condensation, the formation of contrails and additional cirrus clouds in the upper troposphere.

The residence time of freshly generated aerosol in the lower troposphere is of the order of a few days due to removal processes like coagulation, sedimentation, dry deposition, incorporation into cloud droplets, and scavenging by precipitation (wet deposition). Residence times in the upper troposphere can be 1–2 weeks. Figure 2 shows the most relevant processes to (1) aerosol production creating the primary aerosol, (2) the changes the aerosol is subjected to in the troposphere, and (3) the removal processes.

2.3 Stratospheric Aerosols

While tropospheric aerosols and clouds include a wide range of different particle types, the situation is less complicated in the stratosphere. The types of stratospheric aerosol can be categorized as stratospheric sulfate aerosols (SSA) and polar stratospheric clouds (PSC), where the latter are divided into PSC of Type I and Type II. In addition, soot particle injections into the stratosphere from aircraft may play a role.
SSA are formed by a liquid binary solution of H$_2$SO$_4$ and water, and they are present at all altitudes from the tropopause up to about 30 km. Above that altitude the stratospheric temperatures are too high and the H$_2$SO$_4$ partial pressure is too low, such that the droplets would evaporate. In periods during which the stratosphere is not perturbed by heavy volcanic aerosol injections the distribution is relatively similar at all latitudes and the density is of the order of 10 particles cm$^{-3}$ (13,19,20).

PSCs of Type I are believed to be essentially composed of nitric acid in liquid solution, or of solid, or hydrate phase. These particles have sizes with radii of the order of 0.5–2 μm. PSCs of the sub category “Type Ia” are commonly believed to consist of nitric acid trihydrate particles (NAT; HNO$_3$·3H$_2$O). For clouds of the second subcategory “Type Ib”, it is generally accepted that they are formed by supercooled ternary solutions (STS) of H$_2$SO$_4$, HNO$_3$, and H$_2$O, with traces of HCl, HOCl, and possibly some bromine-containing compounds. Type II category PSCs consist of ice crystals, possibly with some HNO$_3$ and H$_2$SO$_4$. These particles are significantly larger having size diameters between 4 and 40 μm. Mass mixing ratios for Type I and Type II PSCs are in the order of 10 and 1000 ppbv, respectively. Other hydrates like sulfuric acid tetrahydrate (SAT), nitric acid monohydrate or nitric acid dihydrate (NAM, NAD) could also occur because these are thermodynamically stable under stratospheric conditions.

Soot is found in the lower stratosphere and its presence can be particularly important due to its potential heterogeneous chemical reactivity and radiative effects. The most important source of soot in the stratosphere is due to commercial air traffic, as confirmed by recent measurements. The maximum concentration of soot in the stratosphere is of the order of 1 ng m$^{-3}$ in the northern hemispheric aircraft corridors around the cruise altitude of the aircraft.

### 2.4 Measurement Techniques

Various aerosol and cloud properties can be measured by means of satellites, airborne instrumentation, ground-based techniques, and particle sampling accompanied by analytical methods in the laboratory. Ground based in situ instruments measure physical and chemical properties of the aerosol on specific locations and constitute point measurements conducted usually for extended periods.

Remote sensing methods measure an optical property of the aerosol and are capable of scanning a specific (often large) volume of air in the vicinity of the station. Similarly, satellite-based remote sensing instruments observe significant portions of the global atmosphere detecting large scale and coarsely resolved distributions of aerosols and clouds.

Satellite observations allow global coverage of aerosols and clouds, which serves as a fundamental input as in the case of weather satellites for meteorological predictions. Global aerosol distributions can be obtained, as for instance with satellite instruments like SAGE (stratospheric aerosol and gas experiment). But remote sensing techniques cannot give a detailed insight into the microphysics and chemistry of the particles. A priori assumptions on particle shape and index of refraction are necessary to retrieve aerosol parameters from the measured optical properties (mostly extinction, or backscatter).

In order to obtain specific physical and chemical aerosol data, sometimes down to the scale of a single particle, airborne techniques have been developed to be deployed on aircraft or balloons utilizing passive and active remote sensing methods, as well as in situ techniques.

Aircraft are versatile enough to allow for experiments inside the PBL, in the free troposphere, and in the lower stratosphere up to altitudes around 21 km. Balloons are susceptible to uncontrolled wind drifts, but capable of reaching much higher altitudes (approximately 40 km) than aircraft.

### 3 AEROSOL INSTRUMENTATION

A coarse categorization of aerosol instruments includes:

1. remote sensing instruments,
2. direct reading in situ methods, and
3. sampling devices followed by, in most cases, sophisticated laboratory analyses.

A second classification divides the instruments into those which detect physical, or optical properties, and those which determine particle chemical composition and chemical properties.

#### 3.1 Remote Sensing Instruments for Satellites, Balloons, and Aircraft

Remote sensing for satellite or airborne deployment may be based on passive sounders or on active probing of the atmosphere.

These instruments are only capable, in most cases, of measuring the properties of large populations of particles, while in situ instrumentation permits individual particle analyses. The components of active remote sensing instruments consist of a transmitter in the optical or microwave bands, a reception antenna, and the data acquisition system. In principle, an electromagnetic pulse is emitted into the atmosphere and the receiving
system detects those parts of the radiation which are scattered back by the aerosol particle population or the hydrometeors present in the air. Typical instruments of this class are RADARs and LIDARs. LIDARs are particularly well suited for aerosol and (thin) cloud detection and characterization, while RADARs are used for (thick) cloud and precipitation measurements. Passive sounders use the sun (or the moon) as a light source performing some kind of optical extinction measurement in most cases.

Generally, remote sensing instruments for aerosol measurements deliver optical characterization of the particle population, movement velocities of hydrometeors, rain hail fall intensities, as well as low resolution particle size distributions under certain circumstances. They are widely used to observe individual, or groups of clouds, and monitor their temporal and spatial evolution. For most of these instruments complex mathematical methods with inherent assumptions, uncertainties, and ambiguities need to be applied in order to convert the measured return signal into the desired physical quantity.

3.1.1 Radio Detection and Ranging Measurements

The RADAR technique was originally developed during World War II for military purposes. It consists of a microwave transmitter, a receiving antenna, and data acquisition electronics. A microwave pulse, generated initially by a magnetron, was transmitted through the atmosphere. The beam was collimated using the same transmitting and receiving antenna to reduce the area of search. A small part of the pulse energy is scattered back from the target and detected by the receiving antenna. The distance of the target is equal to half the time-of-flight of the pulse multiplied by the speed of light. Over the years the RADARs have become more sophisticated and suitable for meteorological applications. Conceptually this is a qualitative improvement, because what was initially only a background noise for the RADAR, became the object of investigation. Since the atmosphere is formed by molecules, aerosols and clouds, clouds and raindrops can become the targets for a RADAR. Meteorological RADARs are used today on aircraft for monitoring meteorological conditions during the flight. A new class of RADARs have been developed in the field of science for the investigation of clouds and rain. Such systems have been studied essentially to obtain information on the atmospheric water budget. The main aim of such systems is to be deployed on satellites thus providing global coverage. Still for many scientific aircraft operations a cloud RADAR can be a useful tool, to operate with other active sensors, like LIDARs. Depending on the electromagnetic band in which such RADARs operate, they may be used to detect clouds (35, 70, or 94 GHz), in the high frequency band, or rain in the low frequency band (10 GHz). RADARs operating at high frequencies permit the detection of the cloud’s droplet population. Therefore they yield estimates for the cloud liquid water content. Since such RADARs operate on much longer wavelengths than the LIDARs, they penetrate much deeper into optically thick clouds with the ability to give more complete information on cloud types like cumulus, cumulonimbus, thunderstorm cells and so on. Comparisons were carried out between the GKSS (Hamburg, Germany) cloud RADAR MIRACLE (Microwave Radar Cloud Layer Exploration) operating at 95 GHz and the GKSS backscattering LIDAR system (BELINDA, Broadband Emission LIDAR with Narrowband Determination of Absorption) in Germany in September 1997. Both systems are ground-based instruments, but the result is of general interest: it appears that in particular conditions of relatively optically thick clouds, the cloud RADAR penetrates much better inside the cloud as expected, while the LIDAR can detect optically thin layers, formed by small particles, which are transparent to the RADAR. A cloud RADAR can give information which is complementary to that obtained by a LIDAR, and the benefits of simultaneous measurements with both are the subject of research. Cloud RADARs are also used to derive information on rain, snow and hail, and precipitation fall rates. Doppler RADARs additionally yield information concerning in-cloud wind velocities. In the presence of precipitation, the strong signal originating from the larger precipitating elements masks the signal from the smaller droplets. To measure rainfall, RADARs in lower wavelength bands have been developed operating in the C or X band, 5 GHz or 10 GHz, and are designed to operate on board satellites. During 1993 the NCAR (National Center for Atmospheric Research) ELDORA (Electra Doppler Radar) was installed on the NCAR’s aircraft during the Tropical Ocean Global Atmosphere (TOGA) Coupled Ocean Atmospheric Research Experiment (COARE) campaign. It was used in the X-band and was a dual doppler RADAR. It was able to collect dual Doppler information as the aircraft flew past or through storms (storm reflectivity and kinematic structure).

3.1.2 The Light Detection and Ranging Technique

Closely related to RADARs and of similar principle are LIDARs. The LIDAR transmitter is a pulsed laser beam in the optical, UV (ultraviolet), or IR spectral range, while the receiving antenna is an optical telescope in connection with one or more detection channels, and a suitable electronic data acquisition and storage system. The optical detectors can be photomultiplier tubes or avalanche photodiodes. The emitted pulse (or sequence of pulses) may be at one single or several different wavelengths, generated by one or several lasers. Since
aerosols have dimensions ranging from 0.001 to a few hundreds of micrometers, the most suitable wavelength depends on the type of particle under investigation. The bulk of the aerosols range in diameters from 0.1 to several micrometers and in this region the most suitable wavelengths are in the visible part of the spectrum.

The LIDAR Equation (1) is:

\[
P(R) = \frac{E}{R^2} A \tau(\beta_{\text{ray}}(R) + \beta_a(R))e^{-2n} \int_0^\infty \left(\sigma_{\text{ray}}(r) + \sigma_a(r)\right)dr
\]

where \(P(R)\) indicates the received power as a function of the distance \(R\), \(E\) is the pulse emitted energy, \(A\) is the receiver’s area, \(K\) is an instrument-dependent constant which takes into account the various losses of the system and \(\tau\) is the length of the laser pulse.

Since they are exposed to visible electromagnetic waves the air molecules scatter the light according to Rayleigh scattering theory. For aerosol particles having dimensions of the order of the wavelength or larger, the scattering is described by the Mie theory. The variables \(\beta_{\text{ray}}\) and \(\beta_a\) are the backscatter cross-sections for molecules (Rayleigh scattering) and for aerosols (Mie scattering). Similarly in the exponent the term \(n\) indicates a possible contribution due to multiple scattering, and \(\sigma_{\text{ray}}\) and \(\sigma_a\) denote the extinction coefficient due to the gas molecules and the aerosols. While the relation between \(\beta_{\text{ray}}\) and \(\sigma_{\text{ray}}\) is well known and can be computed, the relation between the backscatter coefficient and the extinction coefficient for aerosols depends on the specific aerosol, and particularly on the shape of the particles.

The light scattered by molecules \(S_{\text{ray}}\), and hence the received signal, is proportional to the fourth power of the inverse of the wavelength \(\lambda\) (Equation 2):

\[
S_{\text{ray}} \propto \lambda^{-4}
\]

When the light interacts with particles of the size of the wavelength a signal proportional to the second power of the inverse of the wavelength is produced (Equation 3):

\[
S_{\text{M}} \propto \lambda^{-2}
\]

For tropospheric cloud particles in the range 20–100 \(\mu\)m, the optical wavelengths produce a flat response, since such wavelengths are much smaller than the particle size.

A laser pulse propagating in the atmosphere is scattered therefore both by aerosol particles and molecules. The ratio between the signal due to aerosols and the signal due to molecules results (Equation 4):

\[
\frac{S_{\text{M}}}{S_{\text{ray}}} \propto \lambda^2
\]

This means that in order to enhance the difference between the signal due to aerosols from the molecular contribution it is necessary to shift toward larger wavelengths. For particles, ranging from 0.1 to a few micrometers (i.e. aerosols and PSC), wavelengths in the optical region are particularly suitable. For such cases, if the particles are liquid and hence spherical, it is possible, by means of multispectral investigation and Mie theory calculations, to derive the particle size distribution.\(^{28,29}\) For solid aspherical particles general solutions of the Maxwell equations can be obtained for simple cases (i.e. spheroids, Chebyshev particles, etc.) and T-matrix\(^{30}\) calculations can give some indication of particle size.

If the layer is optically thin, then contribution of multiple scattering can be neglected and considered as equal to one, which is certainly the case for stratospheric aerosols, PSC, and generally true for optically thin cirrus clouds.

The variables \(\beta_{\text{ray}}\) and \(\beta_a\) are related to the number of molecules and particles present in the atmosphere, according to the relation (Equation 5):

\[
\beta_a(\lambda, R) = \int_0^{\infty} N_a(r)\sigma_{\text{bac}}\,dr
\]

where \(r\) is the scatter dimension, \(N(r)\) is the number of scattering elements present in the atmosphere having a dimension comprised between \(r\) and \(r + dr\), and \(\sigma_{\text{bac}}\) is the backscattering cross-section. The contribution to backscattering due to the molecular atmosphere (Rayleigh contribution) is given in Equation (6):

\[
\beta_{\text{ray}}(\text{m}^{-1}) = 3.44 \times 10^{-8} \frac{p(\text{mbar})}{T(K)\lambda(\mu\text{m})^{4.08}}
\]

where \(p\) the atmospheric pressure and \(T\) is its temperature. It is possible to derive direct information from LIDAR measurements on the particle size distribution, on the total volume, and total surface of the particles if the contribution due to molecular atmosphere can be separated and subtracted from the total signal. Then, in the case of spherical particles, using multispectral LIDARs, it is possible to invert the LIDAR signatures to obtain the particle size distribution and index of refraction by means of Mie theory computations. A minimum of five wavelengths are necessary. The minimum requirement at one wavelength is that one receiving channel has to be in the plane of polarization of the transmitted pulse, which must be linearly polarized, and one must be in the perpendicular plane. The presence of a depolarized signal from an optically thin medium is indicative of the presence of aspherical particles, and in such a case T-matrix computations or other techniques must be applied. If there is no depolarization, then the different LIDAR signatures, obtained simultaneously, can be processed to derive the optical parameters of the medium, and also information on the particle size distribution. This has already been accomplished by ground-based LIDARs.
and a wide network of multispectral LIDAR systems is presently operating at very different latitudes and longitudes. For cloud particle size evaluation, with particles in the range between tens and hundreds of micrometers, an equivalent set of wavelengths in this range would be necessary. IR LIDARs covering this wide range do not yet exist. In addition to this, for wavelengths in or near the IR, the aerosol signal is much stronger than the molecular signal, but is difficult to detect using currently available detectors unless coherent detection is used, which is still quite a complex technique. This is generally applied only for wind measurements and is not recommended for aerosol detection. Therefore the most suitable and the most used spectral region for LIDAR application is in the visible spectrum between approximately 350–1000 nm.

Calibration of a LIDAR operating in the visible spectrum is relatively simple as the molecular signal can be detected. If the LIDAR is firing upward in the stratosphere, the signal above 25 km is generally caused only by air molecules and is used to calibrate the system. If the system is used only in the troposphere, there are generally areas in the free troposphere where aerosols loading contributing to the LIDAR signal is minimum. The signal detected from this region can be used for calibration. This simple technique avoids the necessity to measure pulse per pulse laser energy and the instrument constant, two quantities which may change either from pulse to pulse or in time. For IR LIDAR systems topographic targets are used as no molecular signal can be detected.

Ground-based LIDARs produce very good climatologies above the ground station, but are limited because they can give information only above the site of observation; this is why a wide ground-based LIDAR network has been established, but horizontal resolution is still nonexistent. Therefore space or aircraft systems have been developed.

A space system can give global coverage of the atmosphere of our planet. The first LIDAR in space, mounted on board the shuttle LITE (Laser in Space Technology Experiment) was equipped with a multispectral LIDAR to monitor tropospheric clouds and aerosols and stratospheric aerosols. The laser transmitter was a Nd-YAG laser operating at the following wavelengths: 1064 nm, 532 nm, 355 nm. LITE flew successfully from September 9 to September 19, 1994 demonstrating the capability of a space LIDAR to measure tropospheric clouds and aerosols from the tropopause to the Earth's surface and even measure stratospheric background aerosol distribution.

On aircraft several LIDARs have been flown since the start of the 1980s. Early in their history LIDARs were used from aircraft to monitor phenomena connected with PBLs, like the tracking of plumes or the monitoring of urban aerosols.

LIDARs have been operated both on tropospheric aircraft and presently on stratospheric aircraft to measure from the aircraft downward (nadir) or upward (zenith). The two operations are quite different. In fact the LIDAR signal, like the case of the ground-based LIDARs, reduces with the square of the distance and because the backscattering coefficients decrease almost by an exponential term with altitude, since they depend on the air density when the LIDAR is looking upward (see the LIDAR Equation 5), but remain almost constant if the pulse is fired downward, as the reduction in the signal by the square of the distance is compensated by the increase in the air density. This is the main reason why for the case of a spaceborne LIDAR, if the pulse can be kept collimated, the great distance of the spacecraft from the atmosphere is not a problem; even from space, eye safety remains one of the main problems when firing a laser, at optical wavelengths, downward.

For tropospheric studies, depending of the flight altitude of the aircraft, both upward and downward looking solutions are possible. If stratospheric measurements have to be carried out, then only the up-looking solution is used.

Finally airborne LIDAR systems have been flown since the mid-1980s. Some examples are: the large National Air and Space Administration (NASA) DC-8 airborne LIDAR systems, used by Browell and co-workers (33, 34) McCormik and co-workers (35, 36) and others (37) which measured stratospheric aerosols, like for instance the very early Pinatubo cloud, PSCs, tropospheric clouds and aerosols. On the ER-2 a small compact LIDAR system was developed by Spinhirne and Hart. (38) Finally coherent LIDARs have also been flown, operating in the 10 μm range. Such systems were mainly devoted to wind measurements, but could also deliver very good aerosol data as a by-product. Vaughan et al. (39) have developed, for example, these types of system. As examples, three European recent airborne LIDAR systems are described in more detail in sections 3.1.2.1, 3.1.2.2 and 3.1.2.3. These three systems represent different concepts of airborne LIDARs: OLEX (Ozone Lidar Experiment), is similar to a ground-based system, but operates inside a pressurized aircraft and needs an operator during the flight; ABLE (Airborne Lidar Experiment) is an automated high power LIDAR, installed in an unpressurized bay of a high altitude aircraft; and finally MAL (Miniaturized Airborne Lidar) is an automated microjoule LIDAR, using a diode-pumped Nd-YAG laser and seems to be one of the most promising technologies for future space operation.

3.1.2.1 The Ozone Lidar Experiment System Among the operational LIDARs are ALEX (Aerosol Lidar Experiment) and OLEX of the German DLR (Deutsches
Figure 3 High altitude PSCs measured from ABLE during the airborne polar experiment–polar stratospheric clouds, lee waves, chemistry, aerosols and transport (APE-POLECAT) campaign held in Rovaniemi (Arctic circle) during the winter 1996/1997. (Courtesy of Giorgio Fiocco, University of Rome.)

Similar LIDARs have been developed in the USA by NASA and mounted the NASA DC-8 for tropospheric and stratospheric studies, as indicated in the previous section. Other airborne LIDARs have been developed by the French Centre National de la Recherche Scientifique (CNRS), as the Lidar Embarked Pour L’étude des Aérosols et des Nuages, de Interaction Dynamique-Rayonnement et du cycle de L’Eau (LEANDRE), used for stratospheric aerosol and PSC measurements.

3.1.2.2 The Airborne Lidar Experiment System for a High Altitude Research Aircraft An example of LIDAR mounted on a stratospheric aircraft is ABLE. Developed for the M-55 Geophysica stratospheric aircraft. This system emits pulses both in the upward and in the downward direction. ABLE was developed by the University of Rome and consists of a flash lamp pumped Nd-YAG laser transmitter. The laser operates with a repetition rate of 10 Hz and produces output energies of 250 mJ at 1064 nm (near IR), 150 mJ at 532 nm (visible), and 70 mJ at 355 nm (near UV) which can be selected depending on the scientific goals. The receiving optics is formed by a 40 cm telescope receiver with the availability of two or more acquisition channels. The transmitted pulse is linearly polarized and an option is implemented to detect the direct and the perpendicularly polarized backscattered light signals. The system operates in a coaxial mode, i.e. the output of the laser beam is coaxial with the receiving telescope. Total overlapping between the FOV of the receiver and the emitted beam is reached after slightly over 1 km. With dimensions of

zentrum für Luft-und Raumfahrt), which have flown on different scientific missions to monitor tropospheric clouds, stratospheric aerosols, PSC, and stratospheric ozone. Such LIDARs are representative of large airborne LIDARs, flying on tropospheric aircraft, which need an operator on board. The OLEX LIDAR is used as an aerosol and ozone LIDAR. It has been mounted the German TRANSALL and the DLR Falcon. The system consists of two laser transmitters: (1) a Nd-YAG laser operating at a repetition rate of 10 Hz in the fundamental, second harmonic, and third harmonic with output energies of 200 mJ at 1064 nm, 120 mJ at 532 nm, and 180 mJ at 355 nm, and (2) a XeCl laser operating at 10 Hz, emitting 200 mJ at 308 nm.

The receiver system is based on a 35 cm cassegrain telescope with a field of view (FOV) of 1 mrad and a focal length of 500 cm. The system uses five detection channels, which are one channel for 1064 nm, two channels for 532 nm in two polarization planes, one channel for 355 nm, and one for 308 nm. The 308 and 355 nm channels are specifically dedicated to ozone profiling in the stratosphere, while the other wavelengths are used for aerosol and cloud monitoring. The acquisition electronics can acquire each single signature, with the lasers firing at 50 Hz repetition rate, and the aerosol distributions measured by the system being available in real time. Thus decisions on measurement strategies can be made on board by means of the LIDAR. The total weight of the system is above 270 kg and the total power consumption above 1.6 kW.

The transmitter is a flash lamp pumped Nd-YAG laser transmitter. The laser operates with a repetition rate of 10 Hz and produces output energies of 250 mJ at 1064 nm (near IR), 150 mJ at 532 nm (visible), and 70 mJ at 355 nm (near UV) which can be selected depending on the scientific goals. The receiving optics is formed by a 40 cm telescope receiver with the availability of two or more acquisition channels. The transmitted pulse is linearly polarized and an option is implemented to detect the direct and the perpendicularly polarized backscattered light signals. The system operates in a coaxial mode, i.e. the output of the laser beam is coaxial with the receiving telescope. Total overlapping between the FOV of the receiver and the emitted beam is reached after slightly over 1 km. With dimensions of
1700 × 900 × 800 mm, and weighing over 250 kg, ABLE is a large instrument, operating fully automated. A computer controls all operations and maintains the acquisition of the data. The LIDAR starts operation when the aircraft has reached a given altitude and the agreement of the pilot is needed to start emitting the light beams. The instrument is mounted in the main bay of the M-55 Geophysica, and by means of a plane rotating mirror it can fire both in the nadir and the zenith direction. In the latter case the laser beam emerges vertically only a little over 1 m from the pilot’s cockpit. Due to the low pressure at high altitude and the low optical density of the high cirrus and PSC, the side scattering of the laser beam poses no hazard for the pilot. Due to the high energy of the system, LIDAR signatures can be obtained up to above 30 km altitudes, when looking upward. From Figure 3 it can be seen that very thin PSC at altitudes up to 29 km can be measured. In the nadir-looking mode, the system can penetrate deeply into relatively thick clouds and in general it is possible to obtain signals from near the Earth’s surface. In its nadir configuration ABLE is designed to be eyesafe in the UV wavelength region. It is not eyesafe in the green at full energy, which can be used for measurements in the zenithal mode. The instrument was flown on the M-55 Geophysica inaugural mission (the Airborne Polar Experiment) in the Arctic in December 1996–January 1997.

3.1.2.3 The Miniaturized Airborne LIDAR A different type of airborne LIDAR is the MAL, which is also mounted on board the M-55 Geophysica. A conceptually similar system was flown before on the ER-2. The aim of the MAL system is to monitor the first 1–2 km above or below the aircraft, a role complementary to a high energy LIDAR like ABLE. Therefore it is necessary that the FOV of the MAL transmitter and receiver overlaps at distances of only a few tens of meters from the instrument. The spatial resolution of the retrieved signal has to be of the order of 50–100 m. In order not to saturate the detector in the near-field range, MAL utilizes a laser diode in the near-IR as a laser source. The laser operates at a high frequency repetition rate (10 kHz). MAL, developed in a joint Swiss–Russian cooperation between the Observatoire Neuchatelier and the Space Research Institute of Moscow, consists of a laser diode operating at 836 nm, with a bandwidth of 7 nm, and 0.8 µJ per pulse. Two detection channels were available to measure the direct signal and the cross-polarized signal. MAL is a compact lightweight instrument, mounted behind the cockpit of the M-55 Geophysica. This type of LIDAR is similar to backscattersondes, with the main difference that it presents a range-resolved signature. MAL flew in the Airborne Polar Experiment in the Arctic on board the M-55 Geophysica aircraft. It operated only at night. The maximum range of the return signal was a kilometer. An upgraded system was designed using a diode pumped Nd-YAG laser. This laser operates in the second harmonic (532 nm) of the YAG output energies in the range of 2 µJ per pulse and a pulse repetition rate of 10 kHz. This permits the use of small photomultiplier tubes with incorporated photon-counting electronics and operation in a spectral range of high sensitivity thus enhancing greatly the operational capabilities of MAL and consequently permitting daytime operation.

3.1.2.4 Backscattersondes Backscattersondes are similar to the microjoule LIDAR. In principle a backscatteronde operates like a MAL, having a low energy optical source and measuring the backscattered radiation from an air volume close to the instrument. The backscattered signal is not range-resolved. Since the scattering volume is close to the instrument, the extinction term in Equation (4) can be neglected and a direct measurement of the backscattering coefficient can be achieved. However, the backscattersonde signals require calibration.

Backscattersondes have been flown on stratospheric balloons for several years. Generally a backscatteronde has a flashlamp as transmitting source and at least two receiving channels at two different wavelengths (e.g. 490 nm and 940 nm, like the type of backscattersonde developed by Hofmann and Rosen at the University of Wyoming, USA). Backscattersondes are produced as small lightweight packages which can be flown on standard ozone sounding stratospheric balloons. The detection of two different wavelengths permits information to be gathered on the particle size.

More sophisticated instruments have been developed which have operated on both balloons and aircraft using as emitting source diode lasers operating at different wavelengths as the light source. An example of such a system is MAS (Multiwavelength Aerosol laser Scatterometer).

A laser scatterometer can simultaneously emit a few polarized laser beams at different wavelengths and can detect the light scattered back towards the instrument by the particles and molecules in the air. The detected backscattered light and its change of polarization (the so-called depolarization) can be interpreted, if combined with OPC measurements, in terms of particle shape and refractive index. The OPCs (see section 3.2.2) measure in situ particle size distributions by means of a light scattering technique. For this, Mie theory has to be applied, which necessarily requires information about the particle’s refractive index and shape. Usually for liquid stratospheric sulfuric acid droplets, justified a priori assumptions concerning these particle properties can be made. However, if the in situ measurements...
take place at ambient temperatures low enough for freezing of sulfuric acid droplets to occur, or close enough to nitric acid hydrate saturation, or water vapor saturation temperatures, similar a priori assumptions cannot easily be made. Then a scatterometer operated on the same platform as the OPC can actually measure particle refractive index and shape. Conversely, the refined interpretation of the data delivered by the scatterometer critically depends on the simultaneously measured particle size distribution.

The laser scatterometer MAS is equipped with three laser diodes contemporarily emitting three 100 : 1 polarized beams in the atmosphere at 680, 780, and 830 nm. The emitted power is about 20 mW for each single laser. The telescope used to collect the backscattered light has a diameter of 120 mm. The atmospheric backscattering is collected by six different channels: three are tuned on the three laser wavelengths at parallel polarization, two are tuned on two laser wavelengths but for depolarized backscattering, and one is to measure the atmospheric background in intermediate wavelengths. The maximum spatial resolution is 200 m. A first prototype of a balloon-borne laser scatterometer has already flown in Antartica and other tests where performed in the Arctic during the Second European Stratospheric Arctic and Middle latitude Experiment (SESAME) campaign with the aim of studying the stratospheric clouds which form in the cold polar stratosphere.

3.1.3 Balloon-borne Optical Instruments for Aerosol Analysis Using Limb Scanning Techniques

The Laboratoire d’Optique Atmospherique (LOA) of Lille in collaboration with the Belgian Institute for Space Aeronomy (BIRA-IASB) has developed two instruments to be flown on stratospheric balloons to obtain information on aerosols and trace gases. These instruments are BALLAD (Balloon Limb Aerosol Detection) and BOCCAD (Balloon Occultation for Aerosol Detection).

The BALLAD (Figure 4) instrument was built at LOA during 1993 to observe the Earth’s limb for stratospheric study. The objective of the instrument forms the Earth’s limb image on a linear charge-coupled device (CCD) detector of 1728 pixels, the vertical FOV of the Earth’s limb image on a linear charge-coupled device (CCD) allows multispectral radiance and polarization measurements to be performed. Two interference filters at 850 and 450 nm are dedicated to aerosol study, a third channel centered at 600 nm is deployed for ozone detection. Three other filters centered at 850 nm are equipped with polaroids rotated by 60° with respect to one other to evaluate the linear degree of polarization of scattered light.

BALLAD is installed on board of the gondola of a stratospheric balloon and operates at the ceiling level of 30 km. Its optical axis, pointing approximately 2° below the balloon horizon combined with its large vertical FOV allows observation of all the stratospheric layers, from the tropopause up to the balloon level, simultaneously with one exposure. The vertical resolution is about 350 m for a balloon ceiling at 30 km and a tangent height equal to 15 km.

Measurements are carried out for solar elevation ranging from 2–10° and the rotation of the gondola around the vertical axis (1/3 rpm) permits BALLAD to observe Earth’s limb for various azimuth angles (angular sampling 16°).

The inversion of the nonpolarized radiance measurements at 850 and 450 nm is achieved at LOA; the inversion of the polarized measurements is being performed at BIRA-IASB. They both work in a single scattering approximation. Assuming that the layers on the line of sight are reasonably homogeneous over a sufficient horizontal extent, the circular scans provide measurements for different scattering angles. The normalized radiance, called reflectance \( r(=L/E) \), where \( L \) is the measured radiance and \( E \) the spectral solar irradiance at the top of the atmosphere, depends on the aerosol extinction coefficient and on the aerosol scattering phase function, as well as the same parameters for molecules. Consequently the directional behavior of \( r \) at a fixed tangent altitude contains information about the phase function multiplied by the aerosol concentration. The retrieval procedure \(^{(47)}\) is based on a nonlinear fit to a Heney–Greenstein function for the azimuthal dependence. The Heney–Greenstein function is a good approximation of the phase function in the forward direction so that the inversion is restricted to the 0–80° scattering angle range, which also allows inhomogeneity effects to be limited.

The data inversion scheme based on the Mill method then provides an aerosol extinction profile versus altitude

---

**Figure 4** Schematic diagram of BALLAD. The filter wheel located between the objective and the detector (a CCD) allows the multispectral radiance and polarization measurements to be made. For measurements of aerosol the 850 and 450 nm interference filters are used. See text for details. (Courtesy of Colette Brogniez, University of Lille.)
and an asymmetry factor profile for each channel, from ca. 12–15 km (depending on the channel) up to ca. 25 km.

The BOCCAD (Figure 5) instrument was built by LOA in 1994 to observe solar occultation through the atmosphere. It is planned to provide useful information for the other LOA experiment RADIBAL (RADIometer BALloon), and to provide a direct comparison with satellite measurements SAGE II and POAM II. The objective forms the Sun’s image on a CCD matrix of 244 × 550 pixels. The vertical and horizontal FOV of the instrument are 10° and 7.5°, respectively. A filter wheel, located between the objective and the detector, allows multispectral measurements to be performed. Three interference filters centered at 850, 780 and 443 nm (i.e. identical to BALLAD with one additional channel corresponding to the POAM II channel) are used for aerosol studies, and a fourth channel at 600 nm is dedicated to ozone detection.

BOCCAD is installed on the same gondola as BALLAD and also operates at the balloon ceiling level. The gondola stops rotating after the BALLAD measurements and the instrument points 2° below the balloon horizon so that the large FOV allows observation of the whole occultation event.

The measurements begin when the solar elevation reaches ca. 2° and the Sun’s image can be obtained almost outside the atmosphere to provide a reference image in each channel. Typically about 300 images are formed successively in each channel during a sunset at high latitudes.

Radiance measurements averaged on a few pixels located in the middle of each Sun’s image are converted into transmission data by using a reference image. These transmissions are a function of the local (solar) time. Knowledge of the Sun’s position with ephemeris allows the time–transmission data to be converted into tangent altitude–transmission data taking into account the atmospheric refraction. The transmission is obtained with 350 m vertical resolution. The inversion is conducted in the same way as was done by LOA with SAGE II and POAM II data: after correction for molecular transmission the 850, 780 and 600 nm channels give the aerosol plus ozone transmission and the 443 nm channel represents the aerosol plus nitrogen dioxide transmission. A Chahine’s inversion procedure gives the global extinction coefficients and the separation of the species can be effected.

1. The 850 nm channel is dominated by the aerosol at the lowest levels (typically 20 km), and then leads directly, for these levels, to the aerosol extinction coefficient. The 443 nm channel, corrected for a weak nitrogen dioxide contribution by assuming a standard profile, gives the aerosol extinction coefficient at all altitudes.

2. The 600 nm channel is dominated by ozone at altitudes higher than ca. 20 km and gives a first estimation of the ozone extinction coefficient. For the lower levels an aerosol correction is needed to derive extinction.

3. A complete ozone profile is then available and this allows retrieval of the ozone contribution from the 850 and 780 nm channels to retrieve the aerosol extinction coefficient at these wavelengths.

4. By refining the spectral variation of the aerosol extinction coefficient at all altitudes, an iterative procedure can be adopted in order to get a better estimation of the ozone extinction.

The data inversion provides aerosol extinction profiles versus altitude for the 850, 780 and 443 nm channels, as well as the ozone number density profile, from the tropopause up to the balloon altitude.

3.2 Airborne in situ Instrumentation for Direct Reading Measurements

A variety of instruments was designed for use on aircraft or balloons in order to measure physical and chemical properties of individual (or small populations of) aerosol particles and cloud elements. The major advantage of airborne instrumentation is that a number of different instruments can be simultaneously carried to a particular atmospheric region of scientific interest. The combined data of the different variables measured by all instruments allow detailed studies of atmospheric physics and chemistry to be conducted.
Optical methods determine the sizes, shapes, thermodynamical phase, and velocity vectors of individual aerosol particles. Additionally particle size distributions and integral properties like number concentrations, particulate surface area, or volume densities, cloud liquid water content, and distributions of particle populations in space are measured optically. By these means it is also possible to obtain the refractive index, the optical extinction, and the backscatter properties of the aerosol. Most in situ direct reading techniques employed on research aircraft, or balloons for aerosol-related measurements, require (1) the representative sampling of the aerosol. The instruments used subsequently for analyses fall into one of the categories: (2) OPCs (3) thermodynamic instruments, (4) other physical techniques, (5) methods requiring particle sampling on substrates and (6) mass spectrometric devices for chemical analyses.

For the deployment of in situ measuring aerosol instrumentation on a fast moving platform particular care has to be exercised concerning the sampling of the particles as it needs to be achieved isokinetically and nondestructively. Certain aspects concerning the sampling are described in section 3.2.1, and the instrument types (2) through (6) are subject of the subsequent sections.

### 3.2.1 Inlets and Nondestructive Aerosol Sampling

Sampling can be performed either directly in the unperturbed free air flow, or sample air containing the aerosol particles can be brought inside the aircraft for analysis through a specially designed inlet. When a parcel of sample air is brought from the free atmosphere to a measuring device through inlets and tubing, it is important to ensure that the sampled air arriving at the measuring instrument has the same characteristics as the undisturbed atmosphere, i.e. in the case of sampling aerosols, the number density of aerosol particles should remain unchanged, like the total surface area, the total volume, chemical particle composition and so on. Since a slowdown of the flow occurs in most inlet systems for aircraft the air is adiabatically heated and this may modify the thermodynamic state and the chemical composition of the particles. For the slower moving balloons this difficulty is not as severe. Additional problems arise as particle size dependent losses to the walls of the sampling inlet and its tubing occur and because impaction losses in curves and bends may alter the representativeness of the extracted air sample. Aerosols and gases may stick to, or are absorbed by, the walls of the tubes. If the tubes are not straight, then deposits of aerosol particles accumulate in bends, and particles from these deposits may be released back into the flow at later times. The vibrational environment of an airplane is especially prone to such “memory effects”. Similar problems are associated with the sampling of reactive gases.

Additional requirements are imposed on the transport system in order to minimize the transit time, thus reducing the alteration introduced to the sample.

An inlet efficiency \( \eta \) is defined for a given particle size as Equation (7):

\[
\eta = \eta_{\text{asp}} \eta_{\text{trans}}
\]

where \( \eta_{\text{asp}} \) is the aspiration efficiency representing for each size the ratio of the concentration of particles entering the inlet to those present in the sampled volume. \( \eta_{\text{trans}} \) represents the fraction of particles of a given size which are transmitted by the inlet.

The inlet can collect air in two different configurations, the isoaerial one, in which the free air flow and the sample flow inside the inlet are aligned, and the anisoaxial one where the two flows occur in nonparallel directions. Particularly on fast moving airplanes, anisoaxial sampling is often connected to the generation of turbulent boundary layers inside the inlet system and boundary layer detachments which should be avoided because of increased turbulent wall deposition losses of small aerosol particles.

The two sampling configurations are further subdivided into three subcategories, which are:

- **Isokinetic sampling**, which occurs when the sample flow gas velocity \( V \) and the free ambient air velocity \( V_f \) are identical, or \( V = V_f \), at the point where the inlet encounters the free air. (Further downstream inside the inlet the flow velocity can be decreased by diffusers etc.) Under conditions of perfect isokinetic sampling the relative ratios of the concentrations of small to large particles are the same in the sample as in the free atmosphere. For isokinetic sampling conditions the \( \eta_{\text{asp}} \) factor is equal to 1 for the axial sampling and below 1 in the case of the anisoaxial sampling. In both cases the transmission losses arise from the gravitational settling of larger particles and from the freestream turbulence inducing wall deposition losses.

- **Supersokinetic sampling**, which is the case \( V > V_f \). Under these conditions the flow velocity \( V \) inside the inlet tip is larger than \( V_f \) outside which is usually due to some pump driving the sample flow through the inlet. The small particles may be able to follow the resulting curved tramlines around the inlet and enter, while the larger, more inert particles may fly by the inlet without entering. Therefore enhancement of the small particles could be introduced as an artefact to the sample. The aspiration efficiency is one or less, limited by its dependency on the ratio \( V_f/V \) for larger particles.

- **Subisokinetic sampling**, which is the case of \( V_f > V \), leads to an enhancement of the larger particles over...
the smaller ones in the sample. For the subisokinetic sampling the aspiration factor will be one or higher, up to a limit depending on the ratio \( V_1/V \) for the larger particles. Transmission losses are due again to the gravitational settling, turbulent wall deposition, and also to the inertial impaction of particles moving toward the inlet internal walls.

During airplane operation un-isoxial sampling often occurs if the angle of attack changes, i.e. in situations when the plane flies in a curve, or when the air flow has a nonzero angle with respect to the aircraft’s longitudinal axis. So-called “shrouded inlets” have been utilized\(^5\) where the inlet performing the representative sampling itself is surrounded by a shroud in order to prevent turbulent boundary layer generation or detachments.

An extreme case of subisokinetic sampling is applied by the so-called CVI\(^5\) for chemical and volatility analyses on the aerosol particles. This inlet permits the collection only of those particles larger than a certain equivalent size radius, while particles smaller than that cut-size, as well as the ambient air, are not permitted to enter the inlet. This is achieved by having the sonde produce a counterflow inside of opposite direction to the free atmospheric flow. Particles larger than the cut-size have sufficient inertia to “overcome” the barrier imposed by this counterflow and enter the inlet, while those particles which are too small are carried together with the air around the inlet tip.

In the Figure 6 the layout of a CVI set-up is shown.

If the instrument flow rate (the so-called return flow rate) is kept constant, then the flow rates define the distance \( L \) where the velocity relative to the sonde’s axis is equal to zero in Equation (8):

\[
L = \frac{F_1 - F_2}{F_1} X = \frac{F_3}{F_1} X
\]

where \( F_1 \) is the return flow rate in L min\(^{-1} \), \( F_2 \) is the sample flow rate in L min\(^{-1} \), \( F_3 \) is the excess flow rate in L min\(^{-1} \), \( R \) is the sonde’s radius in cm, \( D \) is the diameter of the inlet tube in cm, \( X \) is the length of the porous tube in cm and \( L \) is the distance of the tip of the sonde to the stagnation plane inside the sonde in cm.

The cut-size depends on the flow rate, on \( R \) and \( L \).

Particles with inertia sufficient to permit deviation from the stream lines enter the CVI inlet and it is these particles crossing over the stagnation plane which are sampled. In other words, only those particles are collected which travel a distance larger than the so-called “stop-distance” (Equation 9):

\[
d_s > L + g(R)
\]

where \( g(R) \) is a function of the radius of the sonde. \( d_s \) is used to evaluate the “cut-size” of a CVI inlet design, for the different input parameters. In the case of \( g(R) \approx R \) it is possible to compute the dimensional range of the droplets which can be collected with an efficiency close to 50%. For particles larger than 1 \( \mu \)m this results in Equation (10):

\[
d_s = V_\infty \times m_d \times B \times f
\]

where \( V_\infty \) is the air flow velocity in cm s\(^{-1} \), \( m_d \) is the droplet mass \( (4/3)\pi r^3 \rho_d \) in g, \( B \) is the droplet mechanical mobility \( 1/(6\pi\eta_r) \) in St g\(^{-1} \) and \( f \) is a nondimensional correction factor for flows outside of the Stokes regime.

Thus, by a proper dimensioning of the CVI together with proper control of the flow rates, it is possible to sample particles larger than a predefined dimension.

If the air constituting the counter flow is heated and warmer than the ambient air, the CVI does not maintain the characteristics of the sampled particles unaltered. The particles can be forced to evaporate, and subsequent chemical analysis of the resulting gas yields information on the previous chemical composition of the sampled aerosol. The return flow (system flow) is formed by a known air mixture, which is carried on the aircraft in a pressurized tank. The additional trace species detected downstream in the flow then results from the aerosol components which evaporated after passage of the stagnation plane. In the instrumental package developed for the Russian M-55 stratospheric research aircraft, Geophysica, the subsequent chemical analyses are conducted by means of a Lyman-\( \alpha \) and a TDL HNO\(_3\) spectrometer. In the other instrument (right panel) volatile particles and nonvolatile residue particles are counted by the CPC.
of the CVI-generated sample air are performed by a Lyman-$\alpha$ spectrometer,\cite{52} which detects the amount of water vapor present in the sample, by a tunable diode laser absorption spectrometer (TDLAS) for the measurement of nitric acid vapor\cite{53} as well as a variety of other trace gases, and by a two-channel CPC (see section 3.2.3) to count volatile and nonvolatile residual particles in the flow. This instrument package is designed specifically for the purpose of analyzing the chemical composition of PSC cloud particles.

In summary, the design of inlets for representative sampling of aerosols and gases poses a major task for the instrument developer, and sophisticated flow mechanical modeling including particle trajectory calculations, as well as cost intensive wind tunnel studies have to be performed in many cases.

### 3.2.2 Optical Particle Counters

In OPCs the air sample is drawn through an optically sensitive volume such that each individual particle is illuminated by a laser beam. The resulting light reflex scattered by the particle is detected by some optics and the particle size is inferred from the measured light intensity by means of Mie theory, or by the numerical T-matrix method in the case of aspherical particles. Analyzing a large number of particles in this way gives the particle number size distribution (the number of particles of a certain size per volume of sampled air), as well as particulate surface area and particulate volume distribution. From these primary deliverables of the instrument higher order variables can be derived such as total particle number density, surface area and volume densities, as well as the optical extinction, backscattering coefficients and so on. The OPCs for airborne use either adopt a sampling inlet and perform the particle size measurement inside the balloon or aircraft,\cite{54,55} or they conduct the representative detection outside in the free flow.\cite{56} Particle size diameters measured by such instruments typically range from $0.05 - 100 \mu m$, but the whole range is not covered by one single instrument with high resolution. For example the FSSP-300 (forward scattering spectrometer probe model 300, manufactured by Particle Measuring Systems in Boulder, Colorado, USA) detects particles in the free flow outside the aircraft, which have sizes between $0.4 - 23 \mu m$, and classifies them into 31 size bins, while the model FSSP-100 probe equipped with an optical system nearly identical to the FSSP-300 covers particle sizes up to $100 \mu m$ albeit less resolved with respect to size.

As seen in the scheme in Figure 7 the individual particles cross the collimated beam of a He-Ne laser in the particle plane scattering a light reflex into the detection optics. This optical system consists of the right angle prism, collecting lens system, a 50% beam splitter, and...
and two photodiodes as shown in the diagram. The laser beam itself ends on the blind dump spot on the prism such that only light scattered by the particles into an angular cone between 4–12 degrees in the forward direction is intercepted by the detection optics. The two photodiodes, one of which is partially covered by a mask, are necessary in order to ensure that the processing electronics accept only particles which cross the laser beam close enough to the particle plane (Position C in Figure 7). Particles crossing too far away (Positions A and B in Figure 7) are not detected under the scattering geometry given by the 4–12 degree angular cone. The electronics processing the signals from the photodiodes essentially consists of timing, gating, and pulse height analysis circuitry which counts each accepted particle into the 31 “size” bins (more precisely “pulse height bins”) according to the intensity of the particle’s scattered light reflex. As a result the data acquisition system records the number of the size bin for each particle. If proper calibration is available the upper and lower pulse height thresholds of each size bin can be associated with specific particle size diameters. This last step involves the application of solutions for the Maxwell equations (usually from Mie theory) under the boundary conditions given from the scattering geometry and particle and carrier gas properties. These theoretical calculations are subjected to many caveats, as the particle refractive index (real and imaginary parts) must be a priori known (or measured with a different instrument), the particle shape is assumed to be spherical, and the solutions imply various ambiguities over certain size ranges. In the case of aspherical particles Mie theory cannot be used to convert the measured scattered light cross-sections of the particles into the corresponding size, and other numerical methods (as the T-matrix method) have to be adopted.\(^{(57,58)}\)

The most severe disadvantage is the unavailability of the particle refractive index in many experimental circumstances because the upper and lower pulse thresholds for each individual size bin are given from Mie theory and depend critically on the refractive index. Either reasonable assumptions regarding the refractive index need to be made, which is possible for the stratospheric aerosol types, or measurements from systems like MAL or MAS provide the information needed. Modified OPCs became available for use on aircraft which detect the light scattered by individual particles simultaneously under two or several different scattering directions. With these additional signals the size and the refractive index of the particle can be determined as for example by the MASP (Multi Angle Spectrometer Probe).\(^{(59)}\)

The FSSP-300 was deployed on the NASA ER-2 during (Airborne Arctic Stratospheric Experiment) AASE I (1988/89), AASE II (1991/92), and SPADE (1993, Stratospheric Photochemistry Aerosol and Dynamics Experiment), as well as on the Russian M-55 Geophysica high altitude research aircraft during the Airborne Polar Experiment (1996/97) with important results concerning the freezing of stratospheric sulfuric acid droplets and on the evolution of the stratospheric aerosol in the aftermath of the 1991 Mount Pinatubo volcanic eruption. At the speed of 200 m s\(^{-1}\) the OPC acquires particle size distributions in 10 s averaging periods in order to keep errors due to count statistics small. Thus the system provides a spatial resolution of 2 km in the horizontal direction. Since 1994 the MASP has been utilized on the ER-2.

### 3.2.3 Thermodynamic Instruments

The smallest particles (condensation nuclei or Aitken particles) encountered in the atmosphere in the nanometer size range cannot be detected and sized easily by means of OPCs. Thermodynamic instruments like CPCs are widely used to measure the small particles. In these instruments an air sample flow containing the aerosol particles is at first ducted through a saturator unit, where the air is supersaturated with butanol or other suitable vapors. Afterwards the supersaturated air passes through a condenser unit where the air is cooled such that the supersaturated vapor condenses onto the aerosol particles. The particles then grow, attaining sizes large enough to make them amenable to optical detection. In the detection unit following downstream the grown particles are individually detected by means of a simple OPC similar to those described above. Thus the instrument delivers a time series of total particle concentrations. The most critical parameter of such instruments is the lower particle size detection limit which is influenced by many different instrument parameters and is determined experimentally for the most part.

As the particles are grown from subdetectable sizes to sizes above the optical detection threshold a size differentiation is not possible because the original particle size is masked during the condensation process. However, a sequence of simultaneously operating CPCs with different lower size detection limits can provide some coarse size resolution. Of course the CPCs will also count all particles which are larger than 0.05 \(\mu\)m and which could be detected directly by an OPC, but under atmospheric conditions the number of these ”coarse particles” is small compared with the number of Aitken or fine particles and the error introduced is small. On the American high altitude research aircraft ER-2 condensation nuclei counters have been operated\(^{(60,61)}\) addressing the scientific issues of new particle formation by GPC in the tropopause region, the new particle formation and coagulation in the stratosphere after
the Mount Pinatubo eruption in June 1991, and the question how the global Junge aerosol layer is created and maintained.

3.2.4 Other Physical Techniques for Airborne Aerosol Measurements

For those atmospheric aerosol particles larger than 50 µm other optical techniques are adopted for aircraft implementation. These include imaging techniques as realized by one- or two-dimensional optical array probes (Particle Measuring Systems, Boulder, Colorado, USA). These linear photo diode arrays are exposed outside the aircraft’s boundary layer perpendicular to the flow. Shadow cast images from individual cloud droplets and hydrometeors are projected on the photodiode detector by means of He-Ne or diode laser illumination. The number of diodes shadowed by a hydrometeor depends on the particle size and the instrument delivers size and concentration estimates. If the data from the one-dimensional array are read at a fast rate as some large hydrometeors passes through, the time series essentially provides a two-dimensional image of the hydrometeor. For particles larger than 50 µm, size and crystal habit can be resolved by such instruments.

Holographic methods have been used on aircraft in order to record in situ holograms of small volumes of cloudy air (approximately 1 L) containing aerosol particles cloud droplets and hydrometeors utilizing pulsed ruby lasers. Once recorded on the airplane a three-dimensional stationary reconstruction of the original scene can be obtained in the laboratory by means of these holograms. This image can be analyzed aided by a suitably designed reconstruction device with an automated or a semi-automated algorithm. With this methodology the sizes, shapes, distances between droplets, and velocity vectors of each individual hydrometeor can be retrieved\(^{62,63}\) for all objects with size diameters larger than 6 µm.

Other methods usually applied in the laboratory have been modified for use on aircraft. Among these are differential mobility analyzers (DMA), diffusion batteries (DB), aerodynamic particle sizers (APS), Aitken nuclei counters (ANC), cloud nuclei counters (CNC) and ice nuclei counters (INC), nephelometers, optical extinction cells and a variety of others. Detailed descriptions of these instruments are beyond the scope of this section. Their physical principles and applicability for airborne atmospheric measurements are the subject of various chapters in Hinds\(^5\) and Willeke and Baron.\(^6\)

Most of the instruments described in section 3.2.2 through to section 3.2.4 need careful calibration or determination of instrument characteristics before they can be used for atmospheric in situ measurements. This involves, in many cases, sophisticated laboratory technology, for example for the generation of test aerosols with known size, optical properties and sometimes chemical composition. For the size calibration of OPCs, monodisperse aerosols (i.e. a population of particles with identical sizes) of a variety of sizes are needed covering the whole detection range of the OPC. This constitutes a difficult task especially for particles larger than 10 µm. For some instruments it is desirable to generate a known number concentration of test particles, which is also difficult. For CPCs it is necessary to determine experimentally the so-called “efficiency curve”, which characterizes for each particle size the instrument’s ability to detect accurately the number of particles per sample air volume. To perform these tasks laboratory devices are utilized like aerosol suspension atomizers, spraying devices, vibrating orifice generators, spinning disc atomizers, fluidized bed generators, tube furnace nanometer particle generators, DMAs, aerosol electrometers and others. The basic principles and characteristics of most of these techniques are described by Hinds\(^5\) and Willeke and Baron\(^6\) and details can be obtained from the references therein.

3.2.5 Methods Requiring Particle Sampling on Substrates

Most of the instruments described so far exploit physical principles to obtain information about a particular aerosol property. By these methods usually little or no information concerning the particle chemical composition is obtained, although this knowledge is key to many scientific issues involving atmospheric aerosol. There are several techniques which require the sampling of aerosol particles on matrices like filters, impactor slides, coated or pretreated surfaces, grids for electron microscopy and so on prior to chemical analysis. Impaction devices, filter samplers and other particle collection techniques are used on aircraft in order to sample and preserve aerosol particles, transport them into a laboratory, and subject them to detailed analyses by e.g. ion content, solubility and acidity measurements, by electron microscopy, LMMS, PIXE, radioactive radiation emission measurements, NA, micro Raman spectroscopy, and various mass spectrometric methods (see section 2.1 and Willeke and Baron).\(^5\) Since the airborne part for these methods is mostly confined to the sampling of particles they are beyond the scope of this article and only the wire impactor is included here as example.

Wire impactors with chemically reactive coatings were deployed on aircraft in order to study the chemical composition of the particles. They are designed to be mounted perpendicularly to the free air flow outside the aircraft’s boundary layer. Wire impactors consist of wires with dimensions from a few tens to a few hundreds of micrometers onto which atmospheric aerosol particles
impact and stick during exposure. After exposure the impactor is recovered and housed in a sealed container. In the laboratory the collected particles are analyzed with an electron microscope or by other techniques. Coatings which are chemically reactive have been deposited on the wires prior to the in situ exposure (see e.g. Pueschel et al.)\textsuperscript{64} such that particles of a certain composition undergo reactions with the substances of the coating.

The impaction efficiency as a function of particle size and the sticking efficiency of the particles on the wire cause uncertainties in these measurements and therefore other instruments (e.g. OPCs) are commonly deployed simultaneously on the research aircraft.

### 3.2.6 Mass Spectrometric Devices for Chemical Analyses

In order to obtain a direct reading, in situ analyses of the chemical composition of single particles or small populations of them, airborne mass spectrometry has become available in conjunction with laser ablation,\textsuperscript{65,66} a method which is similar to LMMS. The particle ambient air containing the particles is sampled through an inlet into the aircraft, where the air is “stripped off” the sample and the particles enter a vacuum (approximately $1.3 \times 10^{-4}$ Pa) through what is called an “aerodynamical lens” or an differentially pumped inlet (DPI). In Figure 8 the following treatment of the aerosol particles is shown schematically. After exiting from the DPI into the vacuum, the particles are sized via laser scattering and then hit by the pulse of an excimer laser (4–5 mJ energy, 3 ns pulse duration) in the source region of a mass spectrometer. The energy deposited on the particle by the excimer laser suffices to ablated ions and molecule fractions from the aerosol particle surface or body. These ablated ions and charged molecule fractions enter into a time-of-flight mass spectrometer (TOFMS), where the mass spectrum of the ion cloud is measured. Subsequent analyses of the mass spectra of single particles or averages over groups of particles yield information concerning the chemical composition of the aerosol. The introduction of the particles to the vacuum requires only times in the order of milliseconds such that the particle chemical composition is not significantly altered during the sampling. The interpretation of the mass spectra obtained is difficult and may imply ambiguities. Since as many as 10 particles can be treated per second in the mass spectrometer and the spectrum of each individual particle is recorded, the amount of spectra and data acquired can become very large during one research flight. For these reasons automated methods for analyses and interpretation are required. The advantage of these individual particle analyses is that it is possible to resolve details of short events during a research flight (e.g. the crossing of aircraft exhaust emission plumes or contrails).

### ACKNOWLEDGMENTS

The authors want to express their gratitude to Dr. Vincenzo Santacesaria of IROE-CNR, of Florence, Italy, who has revised the whole manuscript. He has also given invaluable help with very stimulating and constructive discussions. The authors also want to thank Dr. Colette Brogniez, of the Institute of Atmospheric Optics of Lille, France, for providing figures and revising the part relative to the instruments BALLAD and BOCCAD and Prof. Giorgio Fiocco, of the University of Rome, Italy, for producing the ABLE LIDAR measurements.

1 Introduction

Although emissions from gasoline-powered vehicles have been reduced significantly since the 1960s, motor vehicles are one of the major sources of air pollutants such as volatile organic compounds (VOC), nitrogen oxides (NO\textsubscript{x}), CO, benzene and polycyclic aromatic hydrocarbons (PAH). While VOC and NO\textsubscript{x} are well known to react with sunlight, forming harmful ozone, CO, benzene and PAH are toxic or carcinogenic. The contribution to air pollution by motor vehicles in Germany in 1992 was 70% for NO\textsubscript{x}, more than 50% for VOC and 90% for benzene.

Further reductions in all these components is the goal of gasoline motor development, catalytic conversion systems and improved fuels. These developments all require to be supported by effective exhaust gas-analyzing systems.

4 Potential and Comparison of Different Techniques

1 INTRODUCTION

Quantitative analysis of automotive emissions gives detailed information about a motor’s combustion behavior and gives information about the contribution from traffic to air pollution. Following the introduction, which discusses the problems of exhaust gas analysis, section 2 covers the basics of the physical effects, that the different spectroscopic systems are based on. These physical effects are discussed especially with respect to gas analysis.

Section 3 describes the functioning of different spectroscopic systems, the measuring procedures and different examples of exhaust gas analysis. Simple examples are used to illustrate the functioning of Fourier transform infrared (FTIR) and diode laser (DL) systems. The construction of a completely home-made Raman polychromator is described in detail. Specific problem areas are pointed out. Selected examples of exhaust gas analysis show typical applications of the particular methods.

Section 4 discusses the present and future potential of the systems described.
conditions. In the following years systems for automotive emissions analysis were developed, based in the main on infrared (IR) and Raman spectroscopies. At that time mass spectroscopic systems were of no interest because mass spectrometers could not be coupled directly to the exhaust gas stream. This situation was changed by the development of atmospheric pressure ionization (API) sources, so that nowadays such systems are good alternatives or are used as complementary systems.

2 PHYSICAL FUNDAMENTALS OF ULTRAVIOLET, INFRARED AND THE RAMAN EFFECT

The basis of these optical spectroscopies is the interaction of objects of investigation with electromagnetic radiation. This interaction is possible only when the objects (molecules) are able to work as an antenna for electromagnetic radiation. That is, following irradiation, charges move within these objects. This causes a dipole to change its magnitude, its direction or both.

2.1 Movement of Electrons – Ultraviolet Spectroscopy

The electrons in a molecule can be moved from their atomic positions over the complete molecular framework. For a diatomic molecule this movement will be along the molecular axis. The eigenfrequencies of this movement are very high, due to the small mass of the electrons and the small dimensions of the molecule, and correspond to the frequencies of the ultraviolet (UV) and visible (VIS) spectral regions. Quantum physics describes this process as the excitation of electrons from their electronic ground state to higher electronic levels.

2.2 Movement of Atomic Nuclei – Infrared Spectroscopy

In molecular vibrations atoms, not electrons, move. Consider the case of a diatomic molecule involving two different atoms. The electronic charge is asymmetric and the molecule forms an electric dipole along its axis, which can change its magnitude with the rhythm of incident electromagnetic radiation. The eigenfrequencies of these vibrations, where the relatively large atomic nuclei are moved, are about two orders of magnitude smaller than for electronic movement and correspond to the frequencies of IR radiation. This process is called an excitation of a molecule from a vibrational ground state to higher vibrational levels.

2.3 Combined Electron and Atomic Nucleus Movement – Raman Spectroscopy

When a diatomic molecule consists of two identical atoms, the electric charge is symmetric over the molecule, even while vibrating. Due to the absence of a dipole the molecule cannot absorb IR radiation, even if the frequency of irradiation corresponds to its vibrational frequency. In this case the vibrational energy has to be provided indirectly. A solution to this problem was first suggested by Raman and Krishnan as follows.

Electromagnetic radiation from the UV and VIS spectral regions can enforce electronic vibrations, so that the electrons will partially move over the molecule. This movement will loosen and stretch the bond, and the atoms will start vibrating. In this way the radiation indirectly loses energy to nuclear movement, namely molecular vibrations, while exciting electronic movement. After this interaction the radiation will have less energy – its frequency is lowered by the molecular vibration frequency. The Raman process is not an absorption, but is based on an inelastic scattering process. Quantum physics describes this process as the excitation of electrons from the ground state to a virtual electronic state, resulting in excitation of higher vibrational states.

2.4 Discussion

As described above, a change in dipole moment during a molecular vibration can be observed by absorbing IR radiation. If there is no change in dipole moment, the vibration can be excited indirectly by UV/VIS radiation, resulting in Raman scattering.

Any molecule has $3N$ degrees of freedom for movement, where $N$ is number of atoms. Subtracting three degrees for translation and three degrees for rotation (or two for a linear molecule), gives the number of vibrational modes. Therefore the linear CO$_2$ molecule has $3N - 5 = 4$ vibration modes (Figure 1).

In the symmetric vibration mode, both bonds are stretched simultaneously and the vibration is a Raman-active one. Both dipole moments, left and right in the molecule, are equal in magnitude and in opposite directions. The resulting dipole moment for the whole molecule is therefore zero and this vibration is not IR active.

In the asymmetric vibration mode, the bonds are not stretched simultaneously and the vibration is not Raman active. However, one dipole will increase as the other gets smaller, so that there is a resulting dipole moment (changing its direction in the rhythm of vibration) and this vibration is IR active.

The deformation vibrations (Figure 1) are both equivalent, resulting in identical frequencies and are called
doubly degenerate. These vibrations are Raman inactive but IR active.

Using these selection rules now for the CO molecule shows that the only possible vibration is symmetric and that the molecular dipole is changed. So this vibration is both Raman active and IR active. However, the IR and Raman spectra (Figure 2) are quite different. In the Raman spectrum the vibrational excitation is represented by a small signal at 2143 cm$^{-1}$, whereas the IR spectrum shows two broad signals, below and above that frequency. This is because there are additional selection rules, due to the fact that molecular vibration is always accompanied by rotation. Again, as in the case of vibration, these rules are different for IR and Raman excitation.

The lower part of Figure 3 shows the IR absorption spectrum of CO, but now with much higher resolution than in Figure 2. It can be seen that the broad bands of CO (Figure 2) consist of individual small lines. The upper part of Figure 3 gives the explanation.

If a molecule is excited from the vibrational ground level $v' = 0$ to the upper level $v' = 1$, there is also a change in molecular rotation. In this case the rotational quantum number $J$ will change exactly by $\Delta J = \pm 1$. Therefore, the different rotational states of the vibrational ground state will result in different rotational states of the excited vibrational state, each changing to the next higher (R-branch) or next lower (P-branch) state. Against this, when exciting vibrational states by Raman scattering, the rotational number $J$ will not change, thus $\Delta J = 0$. The Raman spectrum of CO therefore only consists of the small band (the Q-branch) located exactly between the two IR absorption bands, as shown in Figure 2. This principal difference between IR and Raman excitation is very important for multicomponent gas analysis, as this leads to a lot of broad bands (R- and P-branches) in the IR spectrum and it is often difficult to find spectral regions where bands from different components will not interfere. The Raman spectrum consists of
(Q-branch) and normally there is no interference. This can easily be seen by comparing the IR and Raman spectra for the two components CO₂ and H₂O, which are always present in an exhaust gas in high concentrations. With these components the IR spectrum in wide regions is dominated by the broad signals from these components and, especially in the case of low resolution, these signals can obscure those of other components. In most cases this problem can only be solved using high resolution and special evaluation. The Raman spectrum for these components shows only two small signals for CO₂ (the reason that there are two signals, even though there is only one Raman-active vibration, is the so-called Fermi resonance as can be seen in the Raman spectra from exhaust gases in section 3.3.2 and a sharp signal for H₂O at 3652 cm⁻¹, which is outside the spectral region of interest. For completeness and correctness it should be mentioned here that, for some molecules such as N₂ and O₂, during vibrational excitation by Raman scattering different rotational levels can be excited resulting in R- and P-branches (see Figures 24 and 25), but the signals of these transitions are orders of magnitude smaller than for the Q-branch.

Considering the results from IR absorption, it is evident that UV spectra are much more complex, as the transition from the electronic ground state to higher levels is accompanied by vibrational and rotational transitions. The above results can be summarized with respect to a multicomponent gas analysis:

- IR absorption techniques can be used for multicomponent analysis by consideration of interference of absorption bands from different molecular species, requiring high-resolution instruments. Analysis of homonuclear components such as H₂, O₂, and N₂ is not possible, as these molecules do not have a dipole moment.

- UV absorption, except in a few cases (e.g. NO, NO₂, SO₂), leads to spectra having insufficient structure to be useful for selective concentration analysis. Small-band laser systems (frequency-doubled tunable dye laser, optoparametric oscillators) or high-resolution spectrometers with echelle gratings have been developed for the analysis of air pollution. The development of UV absorption-based exhaust gas analyzers may be encouraged when spectral databases, as in the case of IR absorption, become available.

- Raman spectroscopy has the advantage that each molecule has at least one Raman-active vibration mode, so that in principle all exhaust gas species can be analyzed. The problem of the poor quantum efficiency of the Raman effect had to be solved, as described below.

3 TECHNIQUES

As previously mentioned most optical techniques are based on IR or Raman effects. The different types of IR and Raman spectrometers are discussed in sections 3.2 and 3.3. But first we will have a look at traditional systems, which are in widespread use when checking the emission of motor cars with respect to CO and NO₂.

3.1 Traditional Optical Techniques

For applications where only one or few compounds have to be analyzed, nondispersive (ND) systems can be used. This means that the radiation passing through the sample is not decomposed by dispersing optical components such as prisms or gratings. In all cases a relative broad spectral region, which is selected by filters or selective detectors, is used for the measurement. The systems are in widespread use for gas analysis because of their simple construction, which leads to a high optical throughput and so to high sensitivity. They are also compact in design, easy to handle and are not sensitive to working conditions, such as in an automotive workshop. ND systems are based on IR and UV/VIS absorption.

NDIR systems can be classified as single beam and double beam arrangements, each using filters or selective detectors, giving four basic types of NDIR spectrometer. Figure 4(a) shows the design of a double-beam CO analyzer. IR radiation emitted by an IR radiation source (in general a coiled filament) alternately passes the sample cell (where the automotive exhaust gas is pumped through) and the reference cell (filled with a CO-free gas, such as air) and focused to a detector (usually a semiconductor material such as PbSe). The optical filter limits the spectral region of the radiation to the CO absorption band (2000–2250 cm⁻¹). The sector shutter blocks up the two courses of rays alternately, so that there are alternately two signals from the detector, associated with the two paths. If there is no CO in the sample cell, the two signals have the same magnitude. If there is CO in the sample cell, the radiation in this path will be weakened, while radiation through the reference cell will stay constant. The resulting difference of the two signals is directly converted into the CO concentration.

Figure 4(b) shows the arrangement of a single-beam CO analyzer. In this arrangement there is only one path of rays with one cell, the sample cell. By rotating a wheel, two filters (F₁ and F₂) alternately cross the rays path, of which F₁ will only transmit radiation between 2000 cm⁻¹ and 2250 cm⁻¹, while F₂ will only transmit radiation from a small spectral region outside the CO absorption band. In this arrangement F₂ takes the role of the reference cell in the system described above, and the transmitting window of F₂ has to be chosen so that no component

ENVIRONMENT: TRACE GAS MONITORING
of the exhaust gas will absorb this transmitted radiation. If there is no CO in the sample cell, the two signals, alternately produced with the frequency of the rotating filters, will be of the same magnitude. If there is CO in the sample cell, the signal is weakened when F1 is in the path whereas the signal is always the same when F2 is in the path. Again, the difference between the two signals is directly converted into the CO concentration.

Removing the filters in the arrangement of Figure 4(a) and (b) and replacing the semiconductor detectors by frequency-selective detectors (5) leads to the remaining two systems mentioned above.

Changing the filter band to the corresponding absorbance of other compounds gives a system for measuring each exhaust compound having an absorption in the IR region.

Changing the IR radiation source to a UV/VIS radiation source (that is, discharge lamps such as mercury vapor high-pressure lamp, deuterium lamp, continuous-wave xenon lamp, or flashlight xenon lamp) and using the corresponding filters and a photodetector for that spectral region gives, respectively, a nondispersive-ultraviolet (NDUV) and a nondispersive-visible (NDVIS) analyzer. In most cases NDUV/VIS systems work with a filter wheel with a lot of different optical filters, so that by turning this wheel the spectral range can be covered quickly. The application of these analyzers is essential for the quantification of molecules consisting of identical atoms, such as molecules with no absorption in the IR region (see section 2).

ND analyzers can be coupled directly to the exhaust pipe of a motor car, but in each case and especially for IR-based measurements, the exhaust gas has to be filtered to remove soot and water. Such filter systems are directly integrated in commercially available analyzers.

With ND analyzers a large number of gases can be quantified in an on-line measurement; those of interest in exhaust gas analysis are

- CO \(\rightarrow\) IR
- CO\(_2\) \(\rightarrow\) IR
- SO\(_2\) \(\rightarrow\) IR/UV
- H\(_2\)O \(\rightarrow\) IR
- CH\(_4\) \(\rightarrow\) IR
- H\(_2\)O \(\rightarrow\) IR
- C\(_2\)H\(_2\) \(\rightarrow\) IR
- C\(_2\)H\(_4\) \(\rightarrow\) IR
- NH\(_3\) \(\rightarrow\) IR
- N\(_2\)O \(\rightarrow\) IR
- NO \(\rightarrow\) IR
- H\(_2\)S \(\rightarrow\) UV
- C\(_2\)H\(_6\) \(\rightarrow\) IR
- C\(_2\)H\(_6\) \(\rightarrow\) IR
- IR/UV NO\(_2\)
- IR NH\(_3\)
- IR HCHO

### 3.2 Infrared Absorption-based Modern Techniques

The two IR absorption-based systems for analyzing multi-component gas mixtures are FTIR spectrometers and DL spectrometers. Wavelength dispersive IR spectrometers, which record a spectrum step by step, are not suitable for automotive emission analysis, as they take too much time scanning a complete spectrum, especially when high spectral resolution is necessary.

#### 3.2.1 Fourier Transform Infrared Principle

The design of a spectrometer using the FTIR technique is shown in Figure 5. The principal item of such a system is a Michelson interferometer. Consider the IR light source to produce monochromatic light of a wavelength \(\lambda_0\). This light beam is divided at a beam splitter, reflecting 50% to mirror m1 and transmitting 50% to mirror m2. Reflected by the mirrors, the beams are combined again and focused onto a detector, such as mercury cadmium telluride (MCT). If the optical pathlengths are equal, the combining of both will result in constructive interference and the detector will show a maximum signal. By moving mirror m1 there will be a path difference which leads, when a difference of \(\lambda_0/4\) is reached, to total extinction (as the new distance to mirror m1 is passed twice, the real path difference is \(\lambda_0/2\) and adding two waves with pathlengths difference \(\lambda_0/2\) leads to total extinction). Moving mirror m1 continuously with a fixed velocity \(v\), gives a cosine signal with a frequency of \(v/\lambda_0/4\) Hz.

For polychromatic radiation the conditions for constructive and destructive interference are different with
Figure 5 Design of an FTIR spectrometer.

respect to pathlength differences. The detector signal now takes the form of alternating maxima and minima, both decreasing in amplitude, and this interferogram contains all light frequencies. Calculating from the time domain to the frequency domain gives the spectrum of the light source. Figure 6 shows this Fourier transformation for the simple case of a two-line radiator. The interferogram (Figure 6a) can be decomposed into two periodic sine functions of \( t_1 = 1 \) s and \( t_2 = 3 \) s (Figure 6b) and from this we directly get the frequency distribution with two peaks at frequencies 1 Hz and 4 Hz (Figure 6c). In the case that there is an absorption of one frequency by a gaseous compound, its concentration can be calculated using the Beer–Lambert law (Equation 1):

\[
I(\lambda) = I_0(\lambda) \exp(-\alpha l c)
\]

where \( I \) is the intensity of a spectral absorption line, \( I_0 \) is the intensity from the spectrum baseline (where no specific absorption occurs), \( \alpha \) is the specific absorption coefficient, \( l \) is the pathlength and \( c \) is the concentration. The specific absorption line intensities are obtained from spectra databases,\(^6\) which are additionally used for identifying gaseous compounds and for the selection of noninterfering absorption lines.

As mentioned above, the main problem when analyzing complex gas mixtures, such as an exhaust gas, is the interference between the signals from different compounds. Müller et al.\(^7\) have developed and tested algorithms to evaluate such complex IR spectra. The example in Figure 7 shows the complete procedure of evaluation for a multicomponent gas mixture. The measurements were done at a refinery by an open path FTIR spectrometer. Fourier transformation of the interferogram (Figure 7a) gives the complete absorption spectrum (Figure 7b) from which the part of interest can be selected (Figure 7c). The concentrations were determined from reference data\(^6\) and the Beer–Lambert law. The spectra of the single components were calculated with respect to the concentrations to show the excellent agreement to the measured spectrum (see the residue in Figure 7c).

### 3.2.2 Exhaust Gas Measurements using Fourier Transform Infrared Spectrometry

In recent years some FTIR spectrometer systems have been designed specifically for simultaneous on-line analysis of automotive exhaust gases. Hohenberg et al.\(^8\) selected three types for detailed tests at a motor test stand:

- SESAM II (NIC 800 interferometer) – Siemens AG, München, Germany
AUTOMOTIVE EMISSIONS ANALYSIS WITH SPECTROSCOPIC TECHNIQUES

Figure 7: Simultaneous quantification of air pollution by FTIR:
(a) interferogram, (b) complete IR spectrum, (c) spectral parts for quantification. (Reproduced by permission of Wiley & Sons, NY.)

- AMA-FTIR (Mattson interferometer) – Pierburg GmbH, Neuss, Germany
- MEXA-4000FT (Horiba rotary-type interferometer) – Horiba Ltd, Japan.

With these systems nearly all small molecules in an exhaust gas can be quantified, and up to 30 compounds can be detected simultaneously. Owing to the limited resolution of the FTIR spectrometer in use, the quantification of larger molecules, e.g. most hydrocarbons in an exhaust gas, is restricted.

For on-line sampling there is, in principle, only the need for a heated transfer line and a heated sample cell. A special gas-conditioning device is described in detail by Herget et al.\(^9\)

The SESAM device is constructed only for measurements of undiluted exhaust gas (gas temperature 185 °C), the AMA-FTIR for diluted exhaust gas (gas temperature 50 °C), and MEXA-4000FT for both (gas temperature 113 °C).

All systems have to be calibrated. As the concentration of the different exhaust gas compounds can vary over some orders of magnitude, the calibration\(^10\) has to be done with different test gases and different concentrations, to check linearity. A new test gas source has been developed by Quaß and Schilling,\(^11\) where the concentration of the compound of interest is continuously produced and can be varied easily and continuously, so that extensive production of test gases for different compounds and different concentrations is not necessary. When analyzing gas mixtures by FTIR systems for compounds with high concentration one can expect an inaccuracy of about 2%, and for compounds with concentration below 10 ppm of about 10%, with respect to linearity and reproducibility.\(^8\)

The detection limits for different compounds determined for the three FTIR systems by test gas measurements can be taken from Figures 8 and 9.

Measurements on an Otto motor showed that, for the determination of CO\(_2\), CO, NO, NO\(_2\), N\(_2\)O, H\(_2\)O, and NH\(_3\), the FTIR systems are a good alternative to conventional techniques with the advantage of simultaneous measurement. The determination of THC in an exhaust gas from an Otto motor is possible only when the evaluation algorithms are well fitted to the kind of fuel in use. In most cases this determination must be done by FID. However, the development of new algorithms is progressing rapidly.\(^8\)

For diesel motors, in addition to the compounds mentioned above, SO\(_2\) can be quantified. The determination of THC is not possible, because the concentration is almost below 100 ppm. Likewise, the determination of aromatic and alkenic compounds was not possible with the systems tested.

Figures 10 and 11 show examples for quantitative time-resolved on-line measurements of CO, NO, HCHO and NH\(_3\) while running an Otto motor.

A special application of FTIR is testing the efficiency of catalytic activity, as in this case the important compounds are detected in a time-resolved manner, whereas they can only be determined integrally in traditional chemical
analysis. As an example Figure 12 shows the creation of ammonia in a catalytic system.

At the Idaho National Engineering Laboratory Hybrid & Electric Vehicle Laboratory, automotive emissions measurements\(^\text{[12]}\) were made with an FTIR system based on REGA 7000 ( Nicolet) in accordance with the U.S. Federal Test Procedure. To demonstrate the real-time monitoring capability, a Dodge Dakota pickup, driven with liquified natural gas (LNG) and with gasoline, was used. For raw gas measurements the spectrometer was configured with a 4m path length gas cell. The entire sampling apparatus was heated to prevent condensation of water and of higher-molecular-weight hydrocarbons. The complete IR spectrum was obtained using about 1 s intervals and 23 species of the exhaust gas were quantified simultaneously.

Figure 13 shows the THC emissions from the cold-start phase of the test for gasoline and LNG fuel. These THC levels were determined by summing the concentrations of the single hydrocarbons. As one can see, the most hydrocarbon emission occurs in the first minutes, i.e. before the catalytic converter has reached its operating temperature.

Comparing the THC concentration for gasoline fuel and for LNG fuel shows that, for latter, the THC concentration is much higher during the cold phase. This could lead...
to the interpretation that gasoline-fueled cars will affect the environment less. However, detailed analysis shows that the initial spike of unburned hydrocarbons contains 98% methane in the case of LNG fuel, whereas for gasoline fuel the initial spike contains only 43% methane, with the rest being higher-molecular-weight hydrocarbons. It is debatable whether methane, as a global contributor to the greenhouse effect, or the higher-molecular-weight hydrocarbons, as precursors for the formation of local ozone, are more harmful to the atmosphere. However, this example clearly shows that there is an essential need for analyzers with the capability of measuring on-line and providing simultaneous exact determinations of exhaust gas compounds. The standard FID method, which determines THC only, is clearly not sufficient.

Figure 14 shows the simultaneous detection of CO and CO$_2$ for some minutes, beginning with a cold start. The principal CO emissions occur at engine ignition and during the warm-up period of the catalyst. When the catalyst has reached its operating temperature, known as the light-off temperature, the CO concentration suddenly decreases, while the CO$_2$ concentration increases because of efficient conversion of CO into CO$_2$. The small spikes in CO emissions from 200 s to about 250 s are the result of the rapid acceleration, where the engine is fuel rich. In this case there is a stoichiometric excess of fuel over the oxygen present, so that complete oxidation up to CO$_2$ cannot occur. This example shows the ability to monitor such transient events during a driving cycle, so that it is possible to study simultaneously the changes in

Figure 12 Quantification of NH$_3$, SO$_2$, and aromatic compounds during catalyst warm-up. (Reproduced by permission of FVV, Frankfurt, Germany.)

emission due to the different conditions encountered and the sometimes complex relationships occurring between different exhaust compounds.

3.2.3 Laser Photometers with Infrared Diode Lasers

Due to their excellent beam quality as well as high intensity, lasers are ideal light sources for spectroscopic gas analysis. In addition, DL have advantages over other laser systems:

- small dimensions, so that compact spectrometers can be built up;
- available for the complete region of near and middle IR;
- low initial cost and cost of maintenance;
- easily tuneable;
- long life, especially in comparison with gas lasers.

There are some commercial applications of DL photometers\(^{(13)}\) such as continuous determination of ammonia in flue gas or continuous determination of methane on mineral oil platforms. Much recent work has concentrated on systems for automotive emissions measurements.

3.2.4 Measuring Procedure Principles

The design and principles of operation of DL photometers is easy and similar to that of conventional spectroscopics. The DL emission passes a multiple reflection cell and is focused on to a detector (Figure 15). The emission wavelength can be tuned by the laser temperature or by the laser current, the latter being the most simple way. The laser parameters have be chosen so that the emission wavelength is near to an absorption line of the gas compound to be analyzed. If the laser emission is tuned to the absorption line, this line will appear in detected laser intensity (Figure 15). Absorption lines as well as laser lines are extremely small, so that it is difficult to match the selected absorption line. Gas analyzers therefore need a reference sample, such as shown in Figure 16. The reference sample is filled with the

---

**Figure 14** On-line quantification of CO and CO\(_2\) during catalyst warm-up. (Courtesy of the Idaho National Engineering and Environmental Laboratory.)

**Figure 15** Principle of DL measurement.
compound to be analyzed in high concentration and with repeated tuning a suitable absorption line is easily found. This reference signal is used to tune the laser emission reproducibly over this absorption line (Figure 16). The detected signal in the region of the absorption line is used to calculate the concentration from the Beer–Lambert law (see section 3.2.1). Quantitative calibration is done as described for FTIR.

A special IR DL system DEGAS III (dynamic exhaust gas analyzer system) for analyzing exhaust gas was developed at Fraunhofer Institut Physikalische Meßtechnik, Freiburg Germany. The principle of DEGAS III is shown in Figure 17, in which two IR DLs are operated at controlled temperature and current. After combining them to a single beam, the laser beams are split into one reference and two measurement channels. The reference beam serves as an exact control of the laser emission wavelength, as described above. The DLs are operated by current pulses of typically 60 µs duration with a repetition rate of 5 kHz. The tuning range of each laser includes one selected absorption line of the respective molecular species.

As can be seen from Figure 18, the absorption lines become well separated without interference only for low pressures, so that a special sampling device has been developed (Figure 19). With the special cell geometry and the low-pressure conditions, a particle filter is not needed. The exhaust gas is fed into a 2 mm inner diameter tube of a coaxial heat exchanger about 1 m in length. The cell pressure is kept at 50 mbar by the large buffer volume. The windows of the sample cell are made of sapphire and can easily be cleaned, which is necessary once a day. When
sampling diesel engine exhaust gas with a high particulate content, cleaning is required after about half an hour. DEGAS III was conceived for two gas components, which are measured at two sampling locations, yielding four real-time values of concentrations. For an optical pathlength of 30 cm the detection limits are 5 ppm for CH₄, 10 ppm for CO, 100 ppm for NO, and 500 ppm for CO₂ with respect to the selected nonoverlapping absorption lines. Shorter pathlengths are possible with the result of faster response, but then the detection limit increases. Longer pathlengths can be achieved with a multiple reflection cell with a pathlength of 150 cm, resulting in a fivefold lower detection limit.

Calibration and zeroing is performed by flooding the whole analyzer system with a high flow of test and zero gas, which has to be done once a day.

3.2.5 Results

The system was tested during a number of trials in European and US automotive companies by the designers mentioned above, from which some selected results are shown below.

Figure 20 shows concentration profiles for NO and CO emissions taken from behind two different outlet valves from a single-cylinder research engine. Under these conditions the signal-to-noise ratio is better than 50:1, so that the observed variations represent real concentration profiles. Although the emissions of NO are largely synchronous, the CO values show distinct differences. This indicates inhomogeneous combustion due to improper air–fuel mixing. Such results are extremely helpful in optimizing combustion and have not been observable with conventional techniques.

Another result from these measurements is shown in Figure 21, which represents a comparison between NO analysis by a conventional instrument and by DEGAS III. Again, the variations represent real NO level fluctuations and are not due to noise, which is determined during the ignition-off period to be about 150 ppm. In addition to these fluctuations a large peak directly after ignition turn-on is registered, which may be the result of an unusual high temperature during the first combustion cycle. From these tests it is concluded that there is good agreement between conventional and DEGAS III measurements, but DL system provides more detailed information, which is essential for new motor design.

3.3 Exhaust Gas Measurement using Raman-based Analytical Systems

As mentioned in section 2, the Raman process is based on an inelastic scattering of photons by molecules. Thus when electromagnetic radiation passes through a sample the main part will not interact with sample molecules, a minor part will interact by elastic scattering (Rayleigh scattering), and only a very small part will interact inelastically (Raman scattering). The quantum efficiency of the Raman process is therefore very poor. For that reason early Raman spectroscopic analyses of gases was
difficult – for gases, the Raman signals are about three orders of magnitude lower than for condensed media, due to their low density and lack of an internal field. However, this drawback can be compensated by the use of a powerful laser as the light source. In addition, when it is possible to remove dust particles and aerosols from the sample, the proportion of false light will be very small, which allows the employment of technically simple but very sensitive Raman spectrometers. Special types of holographically formed concave gratings have recently become available, which makes it possible to design systems with very large optical throughput and which, in addition, are very suitable for adaption to multichannel detectors.

3.3.1 Design of a Raman Polychromator

The request for large-throughput systems suitable for use with multichannel detectors has been met by various manufacturers of Raman instruments by the provision of mirror mechanisms, allowing the employment of only one monochromator for double or triple systems.\textsuperscript{16,17}

The Raman polychromator shown in Figure 22 was designed for simultaneous on-line measurement at exhaust gases at the Institut for Spectrochemistry and Applied Spectroscopy, Dortmund, Germany. The optical elements were mounted on a cast-iron ground plate. The holographically manufactured concave grating was a Type IV model HG 20 U, 110 mm by 110 mm, 2000 grooves mm\(^{-1}\), by Jobin Yvon. This grating allows the omission of any additional collimator optics in the polychromator (there are many alternative types of gratings available). The detector was a 1205 D SIT with 500 channels from Princeton Applied Research. The width of one channel was 25 \(\mu\)m. For the measurement of gases, the detector was cooled to about \(-15^\circ\)C. The laser was a Spectra Physics Ar\(^+\) laser, and all measurements were performed with the laser line at 488 nm operating at 5 W.

The objectives, both for entrance and exit slit, were combined by three achromatic lenses with a focal length of 80 mm and a diameter of 50 mm (Figure 23a) resulting in powerful optics with an \(f\) number of 0.7. The corresponding data for the field lens are a focal length of 110 mm and a diameter of 50 mm. This lens may be omitted when using a grating which produces a flat spectrum in its focal plane. The laser focus was imaged onto the slit plane with an image ratio of 1:7. Figure 23(b) shows a Raman signal at the detector at various slit widths. For the measurements described, the slit width was chosen to be 500 \(\mu\)m, so that the slit acts only as a sort of optical stop for the suppression of false light from outside the laser focus.

The imaging ratio between the exit plane of the polychromator and the plane of the detector window was 3.5:1. This means that the 12.5 mm width of the cathode array of the detector corresponds to about 45 mm in the exit plane. As the linear dispersion of the grating is 16 cm\(^{-1}\) mm\(^{-1}\) this means that about 700 cm\(^{-1}\) of a spectrum can be detected simultaneously.

3.3.2 Measuring Procedure and Results for Two Different Raman Systems

For stationary measurements using the Raman polychromator described above, a flexible bag containing an evacuated sample cell was filled immediately at the exhaust pipe. After some minutes, when the soot had settled, the cell was opened and filled. This settling of the soot simulates a fairly efficient filtering procedure, which is necessary as mentioned above.

For dynamic measurements a mineral wool covered metallic plait probe was placed into the exhaust with the end of the probe about 50 cm inside the exhaust pipe. The probe was connected by a flexible pipe with a filter, membrane pump (241 min\(^{-1}\)) and an open ended Raman cell. All measurements were performed on a 1.1-l Otto motor of 40 kW rating at 5700 rpm without catalyst.
All signals were related to the signal of N$_2$ of the air as standard, accounting for the spectral sensitivity $k_0$, which was determined according to D’Orazio and Schrader.$^{18}$ The Raman cross-sections of the compounds of interest were taken from the literature.$^{19}$ As the width of the entrance slit was set as mentioned above, the effective halfwidth of the signals was much larger than the physical halfwidth of the bands of the gaseous compounds, i.e. it was approximately the same for all signals. Therefore, the cross-sections could be correlated directly to the peak height of the signals, which facilitates the quantitative analysis considerably. This procedure yields the concentration $c_X$ of compound X directly from Equation (2)

$$c_X = \frac{I_X \sigma_{N_2}}{I_{N_2} \sigma_X} k_0 c_{N_2}$$

where $I_X$ is the signals peak height for compound X, $I_{N_2}$ is the signals peak height for nitrogen, $c_{N_2}$ is the concentration of nitrogen in air, $\sigma_{N_2}$ is the relative cross-section for nitrogen (=1), and $\sigma_X$ is the relative cross-section for compound X (relative to $\sigma_{N_2}$ = 1). As nitrogen is universal and its concentration in air is constant, it is a nearly ideal standard and additional calibration gases are not needed.

The cross-sections for the various compounds are very different. For example, the cross-section for benzene is more than 10 times larger than that for N$_2$, CO, CO$_2$, NO, etc., so that the detection limit for benzene or substituted benzene derivatives is more than 10 times lower.

The spectrum of Figure 24 shows the complete Raman spectrum from an exhaust gas taken with the flexible bag. The measuring time was 1 s and it is appropriate to correlate the signals to atmospheric N$_2$ as the external standard. As the exhaust gas was sampled directly after starting the cold motor with a choke, which decreased the supply of air, the sample shows comparatively high concentrations for low-weight hydrocarbons (50 ppm for ethene, 130 ppm for acetylene and nearly 180 ppm for methane) as well as for CO, O$_2$ and H$_2$. Against this the concentration of CO$_2$ is fairly low. The Raman band at about 1000 cm$^{-1}$ labelled “c” can be assigned to a mono- or metadisubstituted benzene molecule.

Figure 23 (a) The design of the powerful optics and (b) the shape of Raman signal as function of slit width.

Figure 24 Raman spectrum of an exhaust gas, taken with a measuring time of 1 s. a, aromatic hydrocarbons; b, AHC; c, mono- or metadisubstituted benzene ring. (Reproduced by permission of Vieweg Verlag, Wiesbaden, Germany.)
Increasing the measuring time to 20 s enables additional signals to be registered, labelled “*” in Figure 25. Figure 26 shows the spectral region where all signals are exclusively produced by C–H vibrations from aliphatic and aromatic exhaust gas compounds. Although this part of spectrum cannot be used for a precise determination of THC concentration, it is useful in estimating the total number of C–H bonds from all hydrocarbons in an exhaust gas. Although this can suggest the order of magnitude of total hydrocarbon concentration, the true THC concentration has to be calculated by summing the concentrations of all hydrocarbons detected in the exhaust gas.

As mentioned above, dynamic measurements were performed by connecting the Raman sample cell to the exhaust pipe of the car by a transfer line (Figure 27). Raman spectra from the exhaust gas were registered with a time resolution of 1 s, so that the calculated concentrations represent mean values from an exhaust gas volume of about 400 ml. The sample cell was flushed with clean air both before and after exhaust gas measurements for detecting the signal of atmospheric nitrogen (see Equation 2).

Figure 27 On-line measurement with a Raman polychromator. (Reproduced by permission of Vieweg Verlag, Wiesbaden, Germany.)

Figure 28 shows the concentrations of N₂, CO, CO₂, H₂, and O₂ while varying the speed of the motor from 750 rpm to 4000 rpm. These measurement was done after warming up the motor in idling cycle. Figure 29 shows the same components for a cold motor with a choke reducing
the air supply. The reduced air supply can be seen directly from the resulting N₂ concentrations, which are about 4% lower than in case of the warmed-up motor. Furthermore, the nearly reversed concentrations for CO and CO₂, as well as the higher concentration of H₂, demonstrate the extreme motor conditions. It should be mentioned here that similar results would be obtained from the cold motor measurements of a car with catalyst – at least during the first few minutes until the light-off temperature is reached (see section 3.2.2).

A lot of exhaust gas compounds are missed in the measurements described here, even though they should have been in detectable concentrations in the exhaust gas. The reason is that in both cases (static measurement with the bag sample probing and dynamic measurements with a transfer line) the exhaust gas cooled down to room temperature, so that the following compounds could not reach the sample cell:

- water vapor, which condenses in the elastic bag and in the transfer line;
- SO₂, NH₃, and NOₓ which react with condensed water;
- benzene and similar compounds which are adsorbed at the soot particles;
- compounds with low vapor pressures, such as PAH which condense for the most part.

Figures 30–33 show Raman spectra of some of these compounds, mixed in air to demonstrate the potential of Raman measurement, on one hand, and to demonstrate the limit of detection, on the other hand. Figure 30 shows the Raman signal of water vapor in air, taken with measurement time of 1 s. The relative humidity during this measurement was 43%, which means that the signal represents a water vapor concentration of 1%. Figure 31 shows the Raman spectrum of NO₂/air mixture with an NO₂ concentration of 40 ppm and a measuring time of 1 s. The NOₓ species present in an exhaust gas depend critically on the temperature of the gas. In an internal combustion engine the NOₓ should be represented nearly exclusively by NO with concentrations of about 4000 ppm (see Figure 20). Below temperatures of 150 °C, in contact with oxygen, NO will be increasingly converted into NO₂, resulting at normal temperatures in a well-defined equilibrium between NO₂ and N₂O₄. Therefore, the ratio of the concentration of the various NOₓ will depend entirely on the distance between the motor outlet and the measuring point. Although the minimum detectable concentration of the system described here is about 500 ppm at a measuring time of 1 s and consequently much higher than for NO₂ (Figure 31), the Raman measurement should be done directly at the motor to ensure that the NO has not been converted. As can be seen from Figure 31, the resonance-enhanced Raman signal from NO₂ is.
accompanied by a broad fluorescence signal. This signal, increasing with increasing concentration of NO₂, may complicate a quantification.

Figure 32 shows the Raman spectrum of a benzene/air mixture with a benzene concentration of 10 ppm. As the Raman scattering cross-sections will increase with increasing the number of rings we can conclude from
Figure 32, that the detection limits for PAHs will be in the range of some hundred ppb to some ppm.

Figure 33 shows part of the Raman spectrum of ammonia, for an ammonia concentration of 50 ppm in air.

Another Raman experiment for analyzing exhaust gas was done by Brüggemann and Kasal. They used a 0.85 m Czerny–Turner double monochromator (SPEX, Edison NJ, USA), which was modified to a polychromator. The Raman spectra are registered with a charge coupled device (CCD) detector (SI, Gilching, Germany) with 1024 pixels, of which 700 pixels were intensified. After passing through the sample cell, the laser light is reflected into the sample cell again by a concave mirror, so that the laser power is extended to 30 W (using the 514.5 nm line from an Ar⁺ laser). A second option is a high-energy pulsed laser with 20 J per pulse and a pulse width of 4 µs.

On-line measurements were done directly behind the exhaust pipe, after removing water, at a small two-stroke motor with measuring time of 6 s. Figure 34 shows the complete Raman spectrum, which had to be composed from some partial spectra due to the limited detector size.

Figure 35 shows the Raman spectrum of an off-line exhaust gas sample taken from a four-stroke motor. As the measurements were taken about 4 h after sampling, the composition should have changed. A good hint to this changing is the relatively high concentration of NO₂, which is not normally present in an exhaust gas in such high concentrations (see above). It obviously derives from NO, which is the main compound of NOₓ in exhaust gas.

The results of a special Raman application are shown in Figure 36. The quantification of H₂ before and after catalytic reactions can be used for checking the warm-up time, the light-off temperature and the technical constitution of a catalyst. Figure 36 shows the H₂ concentration to be fairly constant when a gas temperature of 90 °C is reached. The catalyst’s light-off seems to be at about 100 °C, where the H₂ concentration in the exhaust gas behind the catalyst rapidly decreases from 0.5% to less than 100 ppm at 135 °C. The warm-up time was determined to be 140 s.

Figure 37 shows the simultaneous quantification of four exhaust-gas components (measured after the catalyst),
Figure 35 Raman spectrum of exhaust gas from an Otto motor, gas sampled in a bag. (Reproduced by permission of FVV, Frankfurt, Germany.)

Figure 36 Quantification of H₂ dependence on exhaust gas temperature, measured before and after the catalytic reaction.

showing their dependence on vehicle speed. The measurements were done at a car test stand simulating town and country driving. The results show the capability of the Raman system to quantify exhaust gas components over four orders of magnitude with a time resolution of 5 s.\(^{(20)}\)

4 POTENTIAL AND COMPARISON OF DIFFERENT TECHNIQUES

ND techniques, as used at NDIR and NDUV/VIS analyzers, are well established and have been legally certified for some years. Their application is restricted to the measurement of one component with relatively low time resolution, so these systems cannot be applied to simultaneous detection of the various exhaust gas compounds and are not able to resolve fast changes in exhaust gas composition.

FTIR spectrometers allow on-line and simultaneous measurement. They are a good alternative to conventional systems such as CO, CO\(_2\), NO, and NO\(_2\) analyzers, and are additionally capable of quantifying low-weight hydrocarbons. They are particularly suited to checking catalytic effects on exhaust gas, as the compounds created by catalytic processes (NH\(_3\), HCHO, HCOOH, NO\(_2\), N\(_2\)O) can be detected very sensitively. With time resolutions of about 1 s the detection limits are in the range of lower ppm. The detection limits can be improved by magnification of the optical path in the sample cell. This improvement has to be purchased by much lower time resolution – halving the detection limit results in a 10-fold lower time resolution. The interference problem may be solved by the development of sophisticated evaluation algorithms, which are in rapid development.

Due to such molecular properties, homonuclear molecules in principle can not be detected.

DL analyzers are now equipped with lasers emitting radiation from the near IR. The detection limits are comparable to that of FTIR systems, but can be improved by at least two orders of magnitude by using DL with emission from the middle infrared (MIR). However, these DL are of limited applicability and problems can occur when special wavelengths are required. In addition they have to be cooled to the temperature of liquid nitrogen and in some cases below. Each component requires a separate DL, and this leads to highly extended systems. New semiconductor materials may enable a middle infrared diode laser (MIRDL) to be developed that can be cooled thermoelectrically or even work at room temperature. Telecommunication systems use DL systems with external resonators. This technique is transferable to the MIRDL and will extend the tuning range, so that several constituents of a gas can be quantified by a single DL. These developments are progressing rapidly. For reasons of high selectivity and high sensitivity, DL measurements should be done on diluted gas samples. This may be a disadvantage for systems intended to analyze raw exhaust gases. Homonuclear compounds cannot be detected.

Raman-based analyzers can quantify exhaust gas components (including the homonuclear compounds H\(_2\), O\(_2\), N\(_2\)) on-line and simultaneously. In principle the measurements can be done in the raw gas stream directly behind the exhaust pipe, without the use of a sample cell, provided the exhaust pipe has an efficient soot filter. The detection limits for benzene and other compounds containing benzene rings are comparable to IR systems. They are higher (10–100 ppm) for other organic and inorganic compounds. The sensitivity can be increased using lasers with emissions in the UV region. As the Raman quantum efficiency depends on the fourth power of the laser frequency, this results in increased sensitivity of about one order of magnitude. Over that, UV radiation may be at or near to absorption bands of exhaust gas molecules, and the Raman signals will be in resonance or preresonance, enhanced to up to five orders of magnitude. If fluorescence occurs, these fluorescence signals may be used for compound quantification as, in general, the fluorescence of gases reveals distinct vibration structures and a consequent gain in specificity. However, as could be seen for NO\(_2\) (Figure 31), fluorescence may also complicate a quantification. At the moment laser sources for that spectral region can be nitrogen, excimer, frequency-doubled dye lasers, or frequency quadrupled Nd\(_3\):YAG laser. The development of a powerful DL, emitting in the violet or UV spectral region, will lead to an analyzer with high sensitivity, no need of calibration gas, easy handling and low price.

In summary, IR DL and Raman systems have great potential for further development, whereas FTIR systems have nearly reached their maximum possible sensitivity.

Differential optical absorption spectroscopy (DOAS) allows the quantitative determination of atmospheric trace gas concentrations by recording and evaluating the characteristic absorption structures (lines or bands) of the trace gas molecules along an absorption path of known length in the open atmosphere. The DOAS technique is characterized by the following: (1) measuring the transmitted light intensity over a relatively (compared to the width of an absorption band) broad spectral interval; (2) high-pass filtering of the spectra to obtain a differential absorption signal and eliminating broad-band extinction processes such as Rayleigh and Mie scattering (RS and MS); and (3) quantitative determination of trace column densities by matching the observed spectral signatures to prerecorded (reference) spectra by, for instance, least-squares methods.

DOAS shares the advantages of most other spectroscopic techniques, including inherent calibration, sub-parts per trillion (ppt) to ppt sensitivity and precision (1–10%), good specificity, wall-less operation, and the capability for remote measurements. In particular, the concentration of very reactive species such as the free radicals OH, NO₃, ClO, BrO, and IO are determined with DOAS. Other species of interest to atmospheric chemistry are also measurable such as SO₂, CS₂, O₃, NO, NO₂, HONO, NH₃, CH₂O, and most monocyclic aromatic hydrocarbons.

A description of the technique is given, and the various modes of operation and light-path configurations are...
explained. The emphasis of this article is on the practical aspects of instrument design, components of DOAS systems, operation of DOAS instruments, and state-of-the-art techniques for the evaluation of DOAS spectra and realistic determination of detection limits. Finally some examples of DOAS applications are given.

1 INTRODUCTION

The quantitative determination of atmospheric constituents by DOAS makes use of the characteristic absorption structures (lines or bands) of trace gas molecules along a path of known length in the open atmosphere. As a spectroscopic technique DOAS has the advantages of inherent calibration, high sensitivity (sub-ppt to ppt, depending on the trace gas) and precision (1–10%), good specificity, wall-less operation, and the capability for remote measurements. The concentration of very reactive species such as the free radicals OH, NO₃, ClO, BrO, and IO can be determined with DOAS. In addition a wide variety of other trace gases is measurable with DOAS at very high sensitivities (mixing ratios in the ppt to parts per billion (ppb) range; Table 1) including sulfur dioxide, ozone, oxides of nitrogen, nitrous acid, ammonia, aldehydes, and a large number of aromatic hydrocarbons.

In contrast to laboratory spectroscopy, the true intensity \( I_0(\lambda) \), as would be received from the light source in the absence of any atmospheric absorption, is usually difficult to determine, as it would involve removing the air from the open light path. This problem is solved by measuring the so-called differential absorption. This quantity can be defined as the part of the total absorption of any molecule rapidly varying with wavelength, in contrast to the total light extinction it is readily observable. Thus DOAS is characterized by:

- Measuring the transmitted light intensity over a relatively (compared to the width of a molecular absorption band) broad spectral interval.
- High-pass filtering of the spectra to obtain the differential absorption signal.
- Mathematically matching the observed spectral signatures to prerecorded information.

#### 2 LIGHT ABSORPTION IN THE ATMOSPHERE, LONG-PATH ABSORPTION SPECTROSCOPY

Quantitatively the absorption of radiation is expressed by the Lambert–Beer law (Equation 1):

\[
I(\lambda) = I_0(\lambda) \exp(-L \sigma(\lambda))
\]

where \( I_0(\lambda) \) denotes the initial intensity emitted by some suitable source of radiation, \( I(\lambda) \) is the radiation intensity after passing through a layer of thickness \( L \), where the species to be measured is present at the concentration \( c \) (Figure 1). The quantity \( \sigma(\lambda) \) denotes the absorption cross-section at the wavelength \( \lambda \). The absorption cross-section is a characteristic property of any species, \( \sigma(\lambda) \) can be measured in the laboratory, the determination of the light pathlength \( L \) is usually trivial. Once these quantities are known the (average) trace gas concentration \( c \) can be calculated from the measured ratio \( I_0(\lambda)/I(\lambda) \) as shown in Equation (2):

\[
c = \frac{\log \left( \frac{I_0(\lambda)}{I(\lambda)} \right)}{\sigma(\lambda)L} = \frac{D}{\sigma(\lambda)L}
\]

where \( D = \log(I_0/I) \) denotes the optical density of a layer of a given species (note that the decadic as well as the natural logarithm are used in the definition of \( D \); here we always use the natural logarithm). Typical optical densities recorded in DOAS applications are \( 10^{-4} \) to \( 10^{-2} \).

Although the attenuation of a light beam by absorption due to atmospheric constituents is in principle described
A comprehensive description of atmospheric absorption is more than one absorbing species present, thus a more neglects other light-extinction mechanisms, in particular:

- Extinction due to RS, i.e. scattering by air molecules. This is not an absorption process; however, light scattered out of the probing light beam will normally not reach the detector, thus for DOAS applications it is justifiable to treat RS as an absorption process with the cross-section \( \sigma_R(\lambda) \approx \sigma_{R0} \lambda^{-4} \) (\( \sigma_{R0} \approx 4.4 \times 10^{-16} \text{ cm}^2 \text{ nm}^4 \) for air).

- Extinction due to MS, i.e. scattering by atmospheric aerosol particles, described by \( N_A \sigma_{M0} \lambda^{-n} \), with the Junge exponent \( n \) in the range 1–4\(^{11}\) and an average absorption cross-section \( \sigma_M \). By similar arguments to the case of RS, MS can be treated as an absorption process, even though it is only partly an absorption process.

In addition, the real atmosphere will usually have more than one absorbing species present, thus a more comprehensive description of atmospheric absorption is expressed in Equation (3):

\[
I(\lambda) = I_0(\lambda) \exp \left( -L \sum (\sigma_i(\lambda)c_i) + \sigma_{R0}(\lambda)\lambda^{-4}c_{AIR} + \sigma_{M0}\lambda^{-n}N_A \right)
\]

where \( \sigma_i(\lambda) \) and \( c_i \) denote the absorption cross-section and the concentration of the \( i \)th species, \( c_{AIR} \) that of air molecules (2.4 \( \times 10^{19} \) cm\(^{-3} \) at 20°C, 1 atm), and \( N_A \) the average aerosol number density. Typical extinctions due to RS and MS at 300 nm are \( 1.3 \times 10^{-6} \) cm\(^{-1} \) and \( 1–10 \times 10^{-6} \) cm\(^{-1} \), respectively.

### 3 Differential Optical Absorption Spectroscopy Principle and Modes of Operation

#### 3.1 Differential Optical Absorption Spectroscopy Principle

As noted in the introduction, DOAS makes use of the characteristic absorption features of trace gas molecules along a path of known length in the open atmosphere. Thereby the problem of determining the true intensity \( I_0(\lambda) \), as would be received from the light source in the absence of any extinction, is solved by measuring the differential absorption. It is defined as the part of the total absorption of any molecule rapidly varying with wavelength and is readily observable as will be shown below. Accordingly, the absorption cross-section of a given molecule is split in two portions (Equation 4):

\[
\sigma_{i}(\lambda) = \sigma_{i0}(\lambda) + \sigma'_{i}(\lambda)
\]

where \( \sigma_{i0} \) varies only slowly (i.e. essentially monotonously) with the wavelength \( \lambda \), for instance describing a general slope, (as for MS and RS), whereas \( \sigma'_{i}(\lambda) \) shows rapid variations with \( \lambda \), for instance due to an absorption line (Figure 2). The meaning of ‘rapid’ and ‘slow’ variation of the absorption cross-section as a function of wavelength is a matter of the observed wavelength interval and the width of the absorption bands to be detected. Introduction of Equation (4) into Equation (3) gives Equation (5):

\[
I(\lambda) = I_0(\lambda) \exp \left( -L \sum (\sigma'_{i}(\lambda)c_i) \right) \exp \left( -L \sum (\sigma_{i0}(\lambda)c_i) + \varepsilon_R(\lambda) + \varepsilon_M(\lambda) \right) A(\lambda)
\]

where the first exponential function describes the effect of the structured differential absorption of trace species, and the second exponential constitutes the slowly varying absorption of atmospheric trace gases as well as the influence of RS and MS (described by \( \varepsilon_R(\lambda) = \sigma_{R0}(\lambda)\lambda^{-4}c_{AIR} \) and \( \varepsilon_M(\lambda) = \sigma_{M0}\lambda^{-n}N_A \), respectively). The attenuation...
factor \(A(\lambda)\) describes the (slowly) wavelength-dependent transmission of the optical system used. Thus Equation (6) defines the quantity \(I_0^0\) as the intensity in the absence of differential absorption:

\[
I_0^0(\lambda) = I_0(\lambda) \exp \left[ -L \sum_i (\sigma_R(\lambda)c_i) \right] + \varepsilon_R(\lambda) + \varepsilon_M(\lambda) \cdot A(\lambda)
\]

The corresponding differential absorption cross-section \(\sigma'(\lambda)\) is then substituted for \(\sigma(\lambda)\) in Equations (1) and (2). \(\sigma'(\lambda)\) is determined in the laboratory (i.e. taken from literature data), just like \(\sigma(\lambda)\). Likewise Equation (7) defines a differential optical density \(D'\) in analogy to Equation (2) as the logarithm of the quotient of the intensities \(I_0^0\) and \(I_0\) (as defined in Equations (5) and (6), respectively):

\[
D' = \log \frac{I_0^0(\lambda)}{I_0(\lambda)} = L \sum_i \sigma'(\lambda)c_i
\]

Atmospheric trace gas concentrations can then be calculated according to Equation (2) with the differential quantities \(D'\) and \(\sigma'(\lambda)\) substituted for \(D\) and \(\sigma(\lambda)\), respectively. Figure 2 illustrates the relationship of \(\sigma(\lambda)\) and \(\sigma'(\lambda)\) and the determination of \(D'\) from a measured spectrum.

In many cases (such as for the free radicals OH and NO\(_3\), see below) total and differential cross-sections are nearly identical. Obviously DOAS can only measure species with reasonably narrow absorption features. Continuous absorptions of trace gases will be neglected by DOAS. However, DOAS is insensitive to extinction processes, which vary only monotonously with wavelength, such as MS by aerosol, dust, or haze particles. Likewise slow variations in the spectral intensity of the light source or in the transmission of the optical system (telescope, spectrometer etc.) are also essentially eliminated.

The DOAS principle can be applied in a wide variety of light-path arrangements and observation modes as sketched in Figure 3.

### 3.2 Long-path Differential Optical Absorption Spectroscopy Using Artificial Light Sources

The most basic arrangement of a light path in the open atmosphere (Figure 4) consists of a detector (coupled to a dispersing device, for instance a spectrometer, and a telescope) looking into the light beam emitted from the light source such as a searchlight. The instrument will average the concentration over this extended volume of air. This is of advantage in applications where average concentration levels are desired. In particular, local influences such as small emission sources (for instance near the instrument site) have little effect on the result of the measurement. However investigations of, for example, fast chemical processes in the atmosphere require small
Differential Optical Absorption Spectroscopy, Air Monitoring by

\[ \text{Column density: } S = \frac{1}{A} \ln \left( \frac{I}{I_0} \right) \]
\[ V = \frac{L}{A} \ln \left( \frac{I}{I_0} \right) \]

**Figure 3** The DOAS principle can be applied in a wide variety of light-path arrangements and observation modes using artificial (a) as well as natural (b–e) light sources. Either the (light-path averaged) trace gas concentration (a, b), the trace gas column density (d, e), or the length of the light path (as in clouds, c) can be determined (GOME, Global Ozone Monitoring Experiment).

measurement volumes. A logistical disadvantage of this arrangement is the requirement to align the optical elements at either end of the light path; also, power is needed at two places.

Although early DOAS instruments were based of this arrangement,\(^{2,3}\) which is still in use in some commercial instruments, a series of variants have been developed.

On variation of this design uses a reflector (usually a corner-cube retroreflector as indicated in Figure 5) in the field to return the light of a source located next to the spectrometer, thus the total light pathlength is twice the distance between light source/spectrometer and reflector. A coaxial merge of transmitting and receiving telescope is usually used.\(^ {4}\) The advantages and limitations are similar to the basic arrangement (Figure 4). However, the power source and delicate alignment is only necessary at the spectrometer/light source site.\(^ {5–8}\) Another advantage is in reducing the effect of atmospheric turbulence on the light beam. This is due to the ability of corner-cube retroreflectors to return the incident light exactly (although with some lateral offset) into the direction of incidence. Because of this last advantage, this arrangement has become the standard set-up for long-path DOAS instruments.

Another alternative is for the path to be folded in a multiple-reflection cell.\(^ {9–12}\) This approach has two main advantages. First, the measurement volume is greatly reduced, thus making the assumption of homogeneous trace gas distribution much more likely to be fulfilled. Second, the length of the light path is easily changed (in known increments of small multiples of the base path, depending on the particular design of the cell). It is therefore possible to keep the length of the light path close to its optimum (section 7) for the atmospheric conditions.

Disadvantages are the more complicated optical design, reflection losses (high reflectivity \( R > 0.99 \) of the cell-mirrors over spectral intervals of several 10 nm are difficult to obtain, in particular for UV), and the high radiation intensity inside the folded light path can cause photochemical reactions with consequent changes in the concentrations of the species to be measured.

### 3.3 Differential Optical Absorption Spectroscopy with Direct Sunlight or Moonlight

The total atmospheric trace gas contents can be observed by using extra terrestrial light sources, namely sunlight or moonlight. From the optical density \( D \) as derived from the recorded spectra, only total column densities

**Figure 4** Simple set-up of a low-resolution DOAS (the searchlight-type light source is not shown).
Figure 5 Typical set-up of a modern low-resolution DOAS. It uses a coaxial merge of transmitting and receiving telescope. An outer ring of the receiving mirror is used as light source mirror, thus emitting a hollow beam. Due to beam divergence the center hole is filled after a short distance. The high-precision retroreflector array returns the light exactly (within seconds of the arc) towards the source; however, due to the lateral offset of the reflected rays and to atmospheric turbulence the reflected light also reaches the center of the mirror acting as the primary of the receiving telescope.

\[ S = c(z) \, dz \] (with \( dz \) denoting an element of the light path) can be derived. An important step in the evaluation of the spectra is the elimination of the strong solar Fraunhofer structure. This is readily done by recording spectra at different solar zenith angles (SZA, \( \vartheta \)) – while the contribution of the earth’s atmosphere then varies proportionally to the airmass factor (AMF, \( A \approx 1/\cos \vartheta \), neglecting the curvature of the earth’s surface), the solar lines stay constant. Thus ratioing two spectra taken at SZAs \( \vartheta_1 \) and \( \vartheta_2 \) will yield a spectrum with the effective AMF \( A_{12} \) given by \( A_{12} \approx (1/\cos \vartheta_2 - 1/\cos \vartheta_1) \). The deviations from the \( 1/\cos \vartheta \) relationship become noticeable at \( \vartheta > 75^\circ \), (where \( A(75^\circ) \) is about 4\% smaller than \( (\cos 75^\circ)^{-1} \)), in particular at \( A(90^\circ) \approx 20 \) instead of infinity.

An interesting application of this technique is the determination of vertical trace gas concentration profiles by taking a succession of spectra during an ascent of a balloon-borne spectrometer. From these spectra the column densities \( S_z \) above the balloon altitude \( z \) can be derived. After conversion into vertical column densities and differentiating, the concentration profile \( c(z) \) can be derived.\(^{13,14}\)

3.4 Differential Optical Absorption Spectroscopy with Zenith Scattered Sunlight

A spectrograph directed to the zenith (Figure 6) observes the optical density of trace gas absorption bands indirectly via the scattering process of the sunlight at different layers of the atmosphere (assuming that the instrument located is north or south of the respective tropic so that it never receives direct sunlight). At large SZAs this involves averaging over the contribution of nearly horizontal rays, that reach the zenith at different altitudes with different intensities and information content about the trace gas layer.\(^{15-17}\) Simplified, the detected light from the zenith can be represented by a most probable light path through the atmosphere defined by the most likely scattering height \( Z_0 \) in the zenith. Typically \( Z_0 \) reaches about 26 km at 90° (327 nm) down to 11 km (505 nm). Thus, the wavelength-dependent beam height allows, in principle, a certain degree of height resolution. Those slant light paths through the atmosphere are quite long under twilight conditions, thus at 90° zenith angle (and 327 nm) a horizontal light path running 600 km through the stratosphere integrates 90\% of the trace gas absorption signature. As in the case of
These advantages come at the expense of relatively difficult sunlight from the measured optical density $D$, only effective (or slant) column densities $S$ can be derived. The effective term indicates the fact that the light reaching the spectrometer is an average over a multitude of rays actually taking somewhat different routes through the atmosphere. The solar Fraunhofer structure is eliminated in a way analogous to the direct sunlight observation.

Modeling the physical process of radiation transport, including RS, refraction and MS, allows the AMF to be determined. As in the case of direct sunlight DOAS, this is defined as ratio of the effective column $S$ and the vertical column density (VCD, $V$) of a given trace gas ($A = S/V$). Typically the AMF increases from values near unity at $\theta = 0$ to $\approx 20$ at $\theta = 90^\circ$. It is a function of SZA and wavelength, and depends to some extent on assumptions of the relative vertical trace-gas, stratospheric-aerosol, and air-density profiles.\(^\text{17–19}\)

DOAS of scattered, rather than direct, sunlight has been applied to the determination of VCDs for $\text{O}_3$, $\text{NO}_2$,\(^\text{20–26}\) $\text{NO}_3$,\(^\text{27,28}\) $\text{OCIO}$,\(^\text{29–33}\) $\text{BrO}$,\(^\text{34,35}\) and ($\text{O}_2$)\(^\text{2}\).\(^\text{36,37}\)

This technique has two major advantages: (1) no adjustment of the telescope direction is required (which is relatively difficult in the case of direct sunlight or moonlight); (2) stratospheric species can be detected even in the presence of (tropospheric) cloud cover. These advantages come at the expense of relatively difficult calculations of the effective light pathlength (see below); in addition, several effects of light scattering in the atmosphere have to be carefully compensated for.\(^\text{38}\)

In a recently developed variant of the zenith scattered sunlight (ZSL) DOAS technique, the off-axis spectroscopy instrument is pointed away from the zenith by an off-axis angle $\Theta$, usually towards the sun (but not looking directly to the sun). The advantages of this arrangement are better sensitivity at very large SZAs ($>95^\circ$) and better sensitivity to tropospheric species; however, the radiation transport calculations are even more complex than in the case of ZSL/DOAS.

### 3.5 Satellite-based Earthshine Differential Optical Absorption Spectroscopy

Spectroscopy of sunlight back-scattered from the earth’s surface and atmosphere allows determination of trace gas column densities in a way similar to ZSL/DOAS. VCDs are derived by applying appropriately calculated AMFs. As the light traverses the atmosphere twice the AMFs are larger than in the case of ZSL/DOAS for the same SZA. In contrast to ZSL/DOAS the instrument cannot determine the part of the trace gas column below tropospheric clouds. Therefore the presence of clouds has to be detected by the techniques described in section 3.6. An example of this approach is the GOME on board the ERS-2 satellite.\(^\text{39}\)

### 3.6 Determination of the Geometrical Photon Pathlength of Cloud-penetrating Sunlight

The usual goal of DOAS measurements is the determination of the unknown concentration of trace gases where the (differential) absorption cross-section and the length of the light path are known. However, Equation (2) can also be solved for an unknown light path $L$ when the concentration of the absorber is known. Using oxygen ($\text{O}_2$), tropospheric ozone, or oxygen dimer ($\text{O}_2$)\(^2\) absorptions the average lengths of photon paths in clouds or haze can be determined.\(^\text{37,40,41}\) Moreover, by analyzing the absorption of individual rotational lines (e.g. of the $\text{O}_2$ a-band around 765 nm) it is possible to infer the distribution of photon pathlengths inside clouds.\(^\text{42}\) These data are of importance in studying the internal structure of clouds or for assessing the solar heating of the atmosphere.\(^\text{43}\)

Once the optical pathlengths $L$ inside clouds are known this information can be used to determine the concentration of interstitial gases, such as ozone or $\text{NO}_2$ in thunderstorm clouds.\(^\text{41,44}\)
4 PRACTICAL DESIGN OF DIFFERENTIAL OPTICAL ABSORPTION SPECTROSCOPY SYSTEMS

Instruments based on spectroscopic techniques have been designed in a variety of ways. Depending on the particular type of measurement desired they consist of the following key components.

4.1 System Components

4.1.1 Light Source

An important requirement for DOAS light sources is a minimum of spectral variation of $I_0(\lambda)$, in particular at the scale of molecular band widths (i.e. below about 1 nm). In other words the light sources should emit white light at high brightness. In use are the following types.

4.1.1.1 Thermal Light Sources such as Incandescent Lamps or Arc Lamps

Criteria are spectral brightness (watts per unit of radiating area and wavelength interval). This quantity is essentially given by the Planck function and thus the temperature $T$ and emissivity $\varepsilon$ of the radiating area ($T \approx 3000\,\text{K}$, $\varepsilon \approx 1$ for incandescent lamps and $T \approx 6000–10,000\,\text{K}$, $\varepsilon \ll 1$ for Xenon-arc lamps). The spectrum of incandescent lamps is very similar to a blackbody radiator. Xenon-arc lamps have a much larger brightness and also emit an essentially smooth spectrum in the spectral range (starting with blue at about 400 nm) into the near-infrared (IR). Although the emitted power is orders of magnitude smaller than from lasers and thermal light sources, the emission only occurs in a relatively narrow band and – more importantly – from a very small area. In fact the energy emitted from a LED per unit area can be comparable with at least an incandescent lamp.

4.1.1.4 Light Sources Outside the Atmosphere

The largest problem with such light sources (sunlight, moonlight, or starlight) is their structured spectra which contain many Fraunhofer lines (section 3.3).

4.1.2 Optical Elements Adapting the Absorption Path to Light Source and Spectrometer

4.1.2.1 Long-path Systems

In long-path or ZSL/DOAS systems a receiving telescope of sufficiently large aperture (usually 150–300 mm) is required to collect the light. The telescope has to be precisely pointed at the light source or retroreflector array (section 3.2), this can usually only be accomplished by active control of the telescope. Note that even a very rigid mounting of the optical building blocks of the system will usually not solve the problem because, due to an ‘El Mirage’ effect, the light path will bend due to changing thermal gradients in the atmosphere. For ZSL/DOAS instruments much smaller telescopes (aperture several 10 mm) are sufficient. In either case the aperture ratio of the telescope must match that of the spectrometer (or of the connecting quartz fiber).

4.1.2.2 Quartz Fibers

Quartz fibers are conveniently employed to connect the receiving telescope to the spectrometer. This arrangement gives freedom in the placing of the components, so that the telescope can be placed outside while the spectrometer is sheltered. However, optical fibers can be an important component, improving the overall sensitivity of the system considerably. Nonuniform illumination of the field of view of the spectrometer can cause residual structures in the spectra, which can limit the minimum detectable optical density to several $10^{-3}$. Introducing mode mixers into the quartz fiber can greatly reduce this effect.

4.1.2.3 Transfer Optics

Transfer optics are frequently needed to match the aperture ratio of the optical building blocks e.g. telescope to spectrometer, quartz fiber to spectrometer or a multireflection cell to the spectrometer.

4.1.3 Spectrometers

Depending on the wavelength and sensitivity requirements, a wide variety of detector designs are used, ranging from nondispersive semiconductor or photomultiplier detectors to spectrograph–photodiode array combinations. A number of spectrometer designs are in use.
4.1.3.3 Czerny–Turner  This design (and its variants) are traditionally selected for DOAS instruments.\cite{5,53} As well as the grating at least two additional reflecting surfaces, the collimating mirror and the camera mirror are required. The additional reflection losses are usually offset by high-efficiency (60–80\%) plane blazed gratings. The wavelength range is readily selected by rotating the grating.

4.1.3.2 Flat-field Spectrometers  Modern holographic grating technology\cite{65} allows the design of spectrometers consisting of only entrance slit, grating, and detector (i.e. optomechanical scanning device or diode array; section 4.1.4). The present low efficiency of most holographic gratings (20–40\%) is approximately compensated by the reduced losses due to the low number of optical surfaces. Although the stray light produced by holographic gratings itself is lower compared to ruled gratings, the higher intensity of unwanted orders may increase the stray-light level of the whole spectrometer. However, the unused orders are also focused and thus are relatively easily removed by light traps. A disadvantage of most flat field gratings is their limitation to a relatively small spectral range that cannot normally be changed.

4.1.3.3 Fourier-transform Spectrometers  Although this type of instrument has been used for IR absorption spectroscopy for a long time, its application for DOAS in the UV–visible spectral range is quite recent.\cite{66}

Regardless of the type of spectrometer selected, stray light requires careful consideration; its significance for DOAS systems is discussed in section 4.2.

4.1.4 Radiation Detectors to Measure $I(\lambda)$ and $I_0(\lambda)$ Spectra

These devices must rapidly measure a spectrum (quasi) simultaneously to minimize the additional noise arising from atmospheric turbulence; good quantum efficiency is also desirable. However, the most significant requirement is the ability to reliably detect relative intensity differences within the spectrum of $10^{-4}$. Presently two different detector designs are in use.

4.1.4.1 Optomechanical Scanning Devices  These scan a section of the dispersed spectrum (typically from several nanometers to several tens of nanometers) in the focal plane of the spectrograph by a moving exit slit. In the most common design a series of slits are etched radially on a thin metal disk (slotted disk) rotating in the focal plane. At a given time, one particular slit serves as an exit slit where the start of a scan is signaled by an IR light barrier. The light passing through this slit is received by a photomultiplier tube (PMT) the output signal of which is digitized by a high-speed analog-to-digital converter (ADC) and recorded by a computer. The signal is adapted to the ADC range by variable preamplifier gain and/or changing the PMT high voltage. During one scan (i.e. one sweep of an exit slit over the spectral interval of interest), several hundred digitized signal samples are taken. Consecutive scans are performed at a rate of typically 100 scans ($\pm 0.1\%$) per second and are digitized into several hundred channels, which are signal averaged by the software (thus individual samples of the signal are recorded at several tens of kilohertz), thereby meeting the requirement to detect very small signal differences. Alternatively, vibrating exit slits can be used. The disadvantages are less uniform scanning speeds and possible influences of the vibration on other parts of the optics.

As a single scan takes $\approx 10\,$ms, the effect of atmospheric scintillations is negligible, because the frequency spectrum of atmospheric turbulence close to the ground peaks at around 0.1–1 Hz and contains very little energy at frequencies above 10 Hz. In addition, typical spectra obtained during several minutes of integration time represent an average over 10000–40000 individual scans. Thus, effects of noise and temporal signal variations are very effectively suppressed; even momentary blocking the light beam (e.g. when a vehicle is driven through the beam) has no noticeable effect on the spectrum.

The main disadvantage of optomechanical scanning of the absorption spectra is the large multiplex loss, as only the section of the spectrum passing through the exit slit reaches the detector. Thus only of the order of 1\% of the light is utilized, which makes relatively long integration times necessary. In addition, the available PMT photocathodes (multialkali, S20) limit the spectral range to the longer wavelengths of the visible range.

4.1.4.2 Solid-state Multichannel Detectors  Solid-state detectors consisting of several hundred individual photodetectors arranged in a linear row are, in principle, far superior for recording absorption spectra. Additional advantages are the absence of moving parts, (nearly) simultaneous sampling of all wavelength intervals, no high voltage is required, and the quantum efficiency (at least in the red and near-IR spectral regions) is better than that of most PMT cathodes.\cite{67} Figure 7 shows the cross-section of a typical silicon photodiode array detector system (using a Reticon RL 1024 R detector chip). It consists of 1024 diodes, each measuring about 0.025 mm × 2.5 mm integrated on a single silicon chip. Depending on the read-out mode, solid-state detectors are distinguished as detector systems (read-out by sequentially connecting each diode individually to the read-out amplifier via a common rail) and charge-coupled devices (CCD; here read-out is performed by shifting the charge through all diodes to a collecting electrode connected to...
Diode array detectors have clear advantages in applications where strong absorptions \((D > 10^{-3})\) occur, or where only low light levels are available (as in zenith scattered light observation of stratospheric species). For the observation of very low optical densities \((D \approx 10^{-2} \text{ to } 10^{-4})\) optomechanical scanning devices give comparable results; however, compared to diode arrays, inferior light utilization necessitates longer exposure times.

### 4.2 Design Considerations

DOAS has become a versatile technique adapted to many different measurements problems. Once the basic arrangement has been selected, various decisions and tradeoffs have to be made in the design of a DOAS system:

- Choice of spectrometer type and the wavelength range (fixed, variable). This choice is largely dictated by the range of species to be measured (see Figure 8 and Table 1).
- Choice of the light path arrangement (long path, folded, see Figure 3). As outlined in section 3.2 this depends on the desired measurement volume, but also on the required wavelength range.
- Choice of light source.
- Choice of detector type (optomechanical or solid-state).
- Determination of the proper tradeoff between light throughput and size, weight, and cost of the optics.
- Proper tradeoff between spectral resolution and size, cost of the spectrometer.

Some guidelines can be given for the last two points. It can be shown that the amount of light received in a long-path DOAS system with sufficiently large optics is proportional to:

- the luminous intensity of the light source;
- the dispersion of the spectrometer;
- the aperture of the spectrometer;
- the area covered by retroreflectors (if applicable).

However, no gain in light throughput is achieved by increasing the power of the light source (at constant luminous intensity) or by increasing the size of the receiving telescope beyond a certain limit.\(^{(71)}\)

Care must be taken that the instrument transmission and the spectral response curve of the detector (as summarized by \(A(\lambda)\) in Equation 6) are only slowly varying functions of the wavelength. The remaining undesired influences on the shape of the spectrum are then eliminated by the mathematical treatment of the spectrum, as discussed in section 6.
Another point that requires careful consideration when designing a DOAS system is spectrometer stray light. Sources of stray light include: light scattered from optical elements (grating and mirrors), reflection of unused diffraction orders off the spectrometer walls, reflection of unused portions of the spectrum from walls near the focal plane, and reflections from the detector surface.\(^{(72)}\)

Stray light tends to be comparatively high in spectrometers filtering a relatively broad wavelength interval from a continuous spectrum, as in DOAS applications. To illustrate this point, consider a typical stray light level of \(10^{-5}\) for a Czerny–Turner spectrometer.\(^{(72,73)}\) This figure gives the fractional light intensity found anywhere in the spectrum, when essentially monochromatic light (e.g. of a He-Ne laser) enters the spectrometer. The actual width of the line seen in the focal plane will then just be equal to the spectral resolution of the instrument. Continuous light entering the spectrometer can be thought of as being composed of a series of lines spaced at center-to-center distances equal to their width (i.e. the spectral resolution of the instrument). As the total spectral range of light entering the spectrometer (for instance 300–600 nm) is of the order of 1000 times larger than the spectral resolution (typically 0.3 nm for a low-resolution DOAS instrument) the level of stray light (per wavelength interval) is roughly three orders of magnitude larger than would be expected from the single line definition usually considered. Thus, in DOAS applications stray light levels \(I_{SL}/I\) are can be expected to be closer to \(10^{-2}\) than to \(10^{-5}\). For example, a stray light level of \(10^{-2}\) would reduce a true optical density of \(D = 1.00 \times 10^{-3}\) to an apparent \(D_{SL} \approx 0.99 \times 10^{-3}\), thus introducing a 1% error into the result.\(^{(71)}\)

Although this might be considered a tolerable error, stray light can become a major problem at short wavelengths because most light sources have their maximum intensity in the visible part of the spectrum with a sharp drop throughout the UV range. Therefore, below about 250 nm the stray light will normally exceed the desired signal, leading to large errors unless additional wavelength-selective elements (e.g. filters) are used.

### 4.3 Example Systems

A state-of-the-art design using a coaxial merge transmitting and receiving telescope in conjunction with an array of corner-cube retroreflectors is shown in Figure 5. Unattended operation is possible by stepper motor-driven change of spectrometer wavelength setting, introduction of shutters and filters into the light path, and activation of a shortcut optics to record lamp intensity spectra. Automatic alignment of the telescope also allows compensation for small movements of the instrument support and diurnal changes in the temperature gradient in the atmosphere. In addition, different light paths can be selected by pointing the telescope to retroreflector arrays mounted at different distances.

The primary mirror diameter and focal length are 300 mm and 1800 mm, respectively. Smaller instruments with accordingly reduced light throughput and sensitivity are commercially available.

Scattered light DOAS systems are in comparison much simpler (Figure 6), only requiring a spectrometer and a small telescope pointed to the zenith. (Note that the telescope cannot improve the brightness of the sky, but rather will reduce the aperture of the system and thus make radiation transport calculations simpler.)

For the measurement of OH radicals a special, high-resolution DOAS system has been developed.\(^{(74)}\) this instrument uses a wide-band dye laser as light source. In combination with a high-resolution spectrometer and innovative measures to reduce the instrument-induced
spectral structures, individual rotational lines of the OH molecule with optical densities of a few times $10^{-5}$ can be recorded at a spectral resolution of about 10 pm. Coupled to a multireflection cell with a base path of 40 m for a total light path of several kilometers the resulting detection limit is of the order of $10^6$ OH radicals per cubic centimeter.

4.4 Software Issues
The operating and evaluation software of a state-of-the-art DOAS system is an essential part of the system. The tasks include:

- Recording and storage of the spectra and associated information such as meteorological data to give at least the air pressure and temperature required to convert measured concentrations into mixing ratios.
- Cycle through measurement sequences (e.g. take atmospheric and background spectra, section 5.1) and calculate the true atmospheric spectra (Equation 8), make measurements in different wavelength regions, switch to different light paths etc.
- Align optics, for instance in long-path systems the telescope has to be precisely pointed at the light source or retroreflector array as described in section 4.1.2.
- Evaluate spectra (section 6) and display trace gas concentrations. This is the most complex task and is frequently performed off-line.

Several software packages have been developed to perform some or all of the above tasks.

5 OPERATION AND CHARACTERIZATION OF DIFFERENTIAL OPTICAL ABSORPTION SPECTROMETRY SYSTEMS

5.1 Typical Measurement Sequences
A complete DOAS measurement involves taking a series of several different spectra. The example given here is for a system using a diode array detector and an artificial light source, but other arrangements follow similar procedures:

1. Record the atmospheric raw spectrum (ARS, denoted $I_M(i)$); several ($N_M$) individual spectra with integration time $T_M$ are usually co-added.
2. Record the background spectrum ($I_B(i)$) with integration time $T_B$. As explained in section 5.2, scattered sunlight might disturb the measurements. A scattered sunlight or background spectrum is taken with the telescope pointed beside the light source.
3. Record the lamp intensity spectrum (LIS, denoted $I_L(i)$). This spectrum is recorded by admitting direct light from the lamp to the spectrometer (using some optics to bypass the light path).
4. Record the dark current (and electronic offset) spectrum ($I_D(i)$). Normalizing the sum of the $N_D$ co-added dark current spectra gives $I_{D1}(i) = I_D(i)/N_D$.

The true atmospheric spectrum $I(i)$ can then be calculated from the above series of spectra from Equation (8):

$$I(i) = \left[ (I_M - N_M I_{D1}) - T_M/T_B (I_B - N_B I_{D1}) \right]$$

where $N_B$ and $N_L$ denote the numbers of co-added background and lamp intensity spectra, respectively.

Note that background spectra need not always be taken and compensated for, for instance at night or at wavelengths below 300 nm where scattered sunlight levels are low. Also, although lamp intensity spectra are always required to compensate for diode-to-diode sensitivity variations (section 4.1.4), it might not be necessary to take one with each ARS.

An altogether different approach to taking lamp intensity spectra is the multichannel scanning technique (MCST). In MCST a series of (typically about 10) ARSs is taken and stored. They are then successively shifted in wavelength (for instance by slightly rotating the grating) in such a way that the spectral information is essentially smoothed out when they are co-added (after subtracting $I_D$) to give a LIS. Now each ARS is divided by the thus obtained LIS and digitally shifted back to the same wavelength position (for instance of the first ARS in the series) to obtain a true atmospheric spectrum. The advantage of MCST is that the diode-to-diode sensitivity variations are even more precisely eliminated, because spectra taken to determine these variations are recorded under precisely the same conditions as the ARS. Measurement time is also saved, as no separate LIS has to be taken.

5.2 Scattered Light with Artificial Light Sources
During daytime sunlight scattered within the measurement volume (not to be confused with stray light inside the spectrometer) may also reach the spectrometer. In contrast to a more or less continuous offset caused by spectrometer stray light, scattered sunlight exhibits the strong Fraunhofer structure (containing signatures of, e.g. stratospheric O$_3$ and NO$_2$; section 3.3), which can disturb measurements even at stray light levels as low as a fraction of a percent of the received light source intensity. Fortunately, due to the very narrow field of view of the instrument (of the order of $10^{-9}$ sr), levels of
scattered sunlight are usually found to be quite low, with the exception of hazy conditions.
In the latter cases, however, the scattered light is easily subtracted from the total spectrum by frequently interrupting the measurement and taking a scattered light (i.e. background) spectrum with the telescope pointed beside the light source. As only an offset of a fraction of a degree is required, this leaves the amount of scattered light entering the system practically unchanged.

In folded light path DOAS systems scattered light from the artificial light source can cause also problems. In arrangements using retroreflector arrays some of the light might be scattered directly into the spectrometer and thus bypass the light path. Fortunately, this type of scattered light is eliminated by the procedure described above.

Somewhat less satisfactory is the situation in multirefection cells. Although the amount of scattered sunlight can be readily determined by blocking the light source, deadjustment procedures to determine the fraction of light bypassing the full light path are difficult to apply.

5.3 Instrument Function

A spectrometer is characterized by its response \( W(\lambda) \) to monochromatic signal. The half-width \( \Gamma_0 \) of \( W(\lambda) \) is frequently called the spectral resolution of the spectrometer. At the typical resolution of a DOAS spectrometer (a few 10ths of a nanometer) atomic emission lines (e.g. of a Hg lamp with typical linewidths of the order of 1 pm) are a sufficiently good approximation to a monochromatic light source. Thus \( W(\lambda) \) can be readily determined for each instrument during the characterization procedure; note that \( W \) might be a function of the wavelength. The instrument function is then used to calculate the proper \( \sigma(\lambda) \) and thus allows reliable absolute calibration of any DOAS instrument (see Equation 9 in section 6.1).

5.4 Residual Spectral Structures

The spectral structures that remain after all known spectral features have been removed from the measured spectrum (see section 6 and Figure 9, bottom trace) can be due to several physical possibilities:

- Absorbing species present in the atmosphere, that are unknown or unaccounted for.
- Unknown instrumental features.
- Random noise (due to photoelectron statistics)

Although the last possibility can be tested for (and can be reduced by co-adding more spectra), the first two may ultimately determine the detection limit of the DOAS system. Techniques for treating residual spectral structures as randomly occurring features are described elsewhere.\(^{(70,79)}\)

Figure 9 Deconvolution process of an atmospheric spectrum (uppermost trace) recorded in Heidelberg on 27 August 1994, with overlapping absorptions due to \( \text{O}_3 \), \( \text{NO}_2 \), \( \text{SO}_2 \), and HCHO (traces 2–5 from the top, note different scales). The least-squares fitting procedure determines the four weighting factors for the above reference spectra in order to model the measured spectrum. From these factor mixing ratios of 16.6 \pm 0.8, 4.6 \pm 0.6, 1.25 \pm 0.02, and 2 \pm 0.3 ppb were derived for the above species, respectively. Further fitted parameters compensate for slight errors in the wavelength–pixel mapping.\(^{(70)}\) In addition a fifth-order polynomial was fitted. The remaining residual spectrum after removal of the absorption structures is shown as the bottom trace.

5.5 Characterizing

The most important steps in characterizing a DOAS system include determination of the following quantities:

- The instrument function \( W \) (and thus the spectral resolution) of the spectrometer.
- The stray light level of the spectrometer.
- The light throughput of the system (e.g. in photons per pixel and per second) under defined conditions (e.g. atmospheric extinction and scattering properties).
- The residual spectral structure of the system.
6 EVALUATION TECHNIQUES FOR DIFFERENTIAL OPTICAL ABSORPTION SPECTRA

As the absorption cross-section $\sigma$ and the light path $L$ in Equation (2) are usually known. In practice two additional problems arise:

- the appropriate differential absorption cross-section must be found;
- the $I_0$ spectrum has to be determined.

In addition, in certain spectral regions overlapping absorptions by several trace species may occur (Figure 9), which must be separated. This problem is discussed in section 6.7.

6.1 Preparation of Reference Spectra

In principle there are two ways to determine reference spectra for DOAS spectrometers. The first uses a reference cell filled with a known amount of the species under consideration in the light path of the spectrometer. This procedure has the advantage that it yields spectra exactly as seen in the atmosphere; however, it is usually practical only for stable species. A cell filled with an unknown amount of a given species can still be used to obtain relative values of $\sigma(\lambda)$ (i.e. values known to a constant factor). Relative reference spectra thus derived can be used in a least-squares fitting procedure (section 6.3) to completely account for the presence of a species in the spectrum. However, in order to determine the concentration of that species, an absolute value for $\sigma$ is required.

In the second method reference spectra taken at a high (in principle infinite) resolution compared to the resolution of the DOAS instrument $\sigma_{\text{hr}}(\lambda)$ are folded with the instrument function $W(\lambda)$ (see section 5.3) to obtain the effective absolute absorption cross-section as seen by the DOAS spectrometer (Equation 9):

$$\sigma(\lambda) = \sigma_{\text{hr}}(\lambda) W(\lambda - \lambda') \, \text{d} \lambda'$$  \hspace{1cm} (9)

The differential absorption cross-section $\sigma'(\lambda)$ is then determined from the thus-calculated spectrum $\sigma(\lambda)$.

6.2 High-pass Filtering of Spectra

The spectrum $I_0$ is found by digitally high-pass filtering the spectra during the evaluation procedure. The cut-off frequency of the filter in wavelength space is chosen so as to minimize attenuation of the molecular absorption bands to be detected. As the width of these bands is roughly 1 nm, this suggests cut-off frequencies of the order of a fraction of a nm$^{-1}$. However, the slowly varying slope of the spectra should be removed as completely as possible. There are many possible choices of suitable filtering techniques:

- Experience shows that the slowly varying light extinction factors $\exp(-\sigma_0(\lambda) c_i)$, $\exp(-\sigma_1(\lambda))$, and $A(\lambda)$ of Equations (5) and (6) are reasonably approximated by a least-squares fitted polynomial $P(l(\lambda) = p_0 + p_1 l + \ldots + p_n l^n$ of suitable order (usually fifth order$^{(3)}$). Thus the expression for $I_0(\lambda)$ given in Equation (6) becomes (Equation 10):

$$I_0(\lambda) = I_0(\lambda) \exp(-L \sum (\sigma_0(\lambda) c_i) + \sigma_1(\lambda)) + \sigma_2(\lambda) \quad A(\lambda) \approx P(l(\lambda))$$  \hspace{1cm} (10)

In the case of only a single absorbing species this corresponds exactly to Equation (1) with $P(l(\lambda)$ as an approximation for $I_0(\lambda)$. Then the optical density $D$ can then be determined from the light intensities at either side of one of the bands as well as in the center of the band (see Figure 2).

- Division by a digitally smoothed copy $S(\lambda)$ of the spectrum can be used instead of dividing by $P(l(\lambda)$.

- Fourier transform techniques have been applied to obtain suitable filtering of the spectra.$^{(66)}$

Note that this filtering procedure is not usually performed as a separate step, but rather as a part of the overall fitting process with $P(l(\lambda)$ sometimes being called a closure term.

6.3 Dealing with Spectral Shift and Changes in Dispersion

Different spectra, even those recorded with the same instrument, may show slightly different wavelength calibration. If $I(i)$ is the recorded light intensity in the $i$th channel (pixel; i.e. photodiode of a detector array, see Figure 1), then in different spectra $I(i)$ might not cover exactly the same wavelength interval $(\lambda(i) - \Delta \lambda, \lambda(i) + \Delta \lambda)$. For instance, the center wavelength $\lambda(i)$ might show a constant offset $\delta \lambda$ for all values of $i$ (which would be called a shift of the spectrum) or, more complicated, the offset $\delta \lambda = \delta \lambda(i)$ could be a function of $i$ itself (usually described by a polynomial $\delta \lambda(i) = a_i \lambda^i$).

Although this effects of spectral shift and squeeze can also be readily compensated by the software, these features introduce additional parameters in the fit and thus increase the uncertainty of the desired trace gas column densities (section 6.6).

6.4 Spectral Fitting Procedures

The central part of spectral evaluation consists of determining the parameters $c_i$ in Equation (3), which are
proportional to the trace gas concentration. In addition, parameters describing the filtering of spectra and spectral distortion (section 6.5) are determined. In essence the spectral fitting procedure models the measured spectra as the sum of reference spectra, a general spectral slope (which slowly varies with wavelength), and possible spectral shift and changes in dispersion. Although only the parameters \( c_i \) of direct importance, the other parameters can also give information, such as the polynomial parameters on the aerosol contents or the parameters describing spectral shift (section 6.3) on drift effects in the instrument.

The fitting procedure can be transformed into a linear problem if \( J(i) = \log(I(i)) \) is modeled instead of \( I \), thus the parameters \( c_k \) describing the trace gas concentrations (or column densities) and \( p_i \), characterizing the polynomial can be obtained by a straightforward matrix inversion procedure.\(^{15,70}\) In contrast, the parameters \( a_i \) that describe spectral shift and distortion (section 6.3) can only be determined by iterative methods, such as Levenberg–Marquardt techniques,\(^{70}\) so that the determination of these nonlinear parameters can easily dominate the processing time in DOAS spectral fitting procedures. Here advanced computational techniques can improve the processing speed by orders of magnitude.\(^{76}\)

### 6.5 Ring Effect and Related Problems with Solar Scattered Light

As discovered by Grainger and Ring\(^{80}\) Fraunhofer lines observed at large SZA's appear somewhat weaker (i.e. are filled in) than the same lines at small SZA's. Meaningful solar scattered light DOAS measurements can only be made if this effect is compensated, otherwise complete removal of Fraunhofer lines by division of spectra taken at small and large SZA's, respectively, is impossible. Fish and Jones\(^{81}\) and Burrows et al.\(^{82}\) present good evidence that rotational Raman scattering is the main cause of the ring effect. As pointed out by Fish and Jones\(^{81}\) the ring effect will also reduce the strength of absorption lines due to atmospheric trace species. This will in particular affect relatively narrow lines (width of the order of the wavelength shift due to rotational Raman scattering, i.e. roughly \( 1 \) nm). For the NO\(_2\) bands around 450 nm the authors calculate an underestimation of the true line strength of up to 7\%; the effects on BrO and OCIO are probably of similar magnitude. In addition, multiple scattering due to aerosol scattering might lead to further underestimation of the absorption line strength and thus the derived trace gas column densities.

Vibrational Raman scattering is also nonnegligible. Its effect is that Stokes lines of O\(_2\) and N\(_2\) of strong Fraunhofer lines will appear as red-shifted vibrational Raman ghost (VRG) lines in the spectrum. It could be argued that those lines are an always occurring part of the Fraunhofer spectrum, but this is not true. First, the angular dependence of RS and Raman scattering are different, so the relative contribution of Raman light is twice as large at SZA = 90\(^\circ\) compared to SZA = 0\(^\circ\). Second, there may be multiple scattering enhancing the VRG. According to calculations by Haug\(^{83}\) VRG may show up as lines with optical densities of up to 0.003.

### 6.6 Realistic Estimation of Errors

The main sources of error in the derived trace gas column densities or concentrations are:
- statistical errors of the fitting procedure;
- uncertainty of the differential absorption cross-section;
- the uncertainty of the AMF (in the case of scattered-light DOAS).

The error of the fitting procedure normally calculated assumes that the noise in the spectra follows a Gaussian distribution and that the individual pixels are statistically independent. Both criteria are only approximately fulfilled; for instance, low-path filtering of a spectrum (digital smoothing) prior to the fitting procedure will increase the correlation between the individual channels and thus lead to a gross underestimation of the statistical fit error.

In addition the effects of spectral shift and squeeze, although readily compensated by software, introduce additional parameters in the fit and thus increase the uncertainty of the desired trace gas column densities.

A detailed analysis of the problem, taking the above point into account, shows that the true uncertainty of the optical density due to a given trace gas might be several times larger than the statistical error of the associated fitting parameter alone.\(^{70}\)

The problems of aliasing are well known from many areas of electronic signal evaluation. It will arise in cases where the spectral resolution is too high for a given number of detector pixels in the focal plane of the spectrometer. Although it is tempting to make “best possible use” of a given number of pixels, there must be a sufficiently large number of signal samples \( I(i) \) (or detector pixels) across one resolution interval. Sample calculations show that about 5–10 samples per resolution interval lead to acceptable errors.\(^{70,84}\) In principle advanced interpolation techniques could be used to correct for this problem (to some extent), but to the author’s knowledge this has not yet been attempted in DOAS spectra evaluation.

### 6.7 Interferences

If the absorption features of several species overlap in the same spectral region, a simultaneous least-squares
fit of the respective absorption spectra is usually used to separate the contributions of the individual species (section 6.4). The fit coefficients will then be a measure for the \( \alpha \sigma_{\text{ck}} \) products of the absorbing species. As Equation (2) is nonlinear in intensity \( I \), the logarithm of \( I(\lambda)/I_0 \) is usually formed, thus allowing a (mathematically simpler) linear fit.

Examples of the deconvolution process are shown in Figures 9 and 10. Figure 9 shows a deconvolution process of an atmospheric spectrum (uppermost trace) recorded in Heidelberg on 27 August 1994 with a 7.5 km light path, with overlapping absorptions due to \( \text{O}_3, \text{NO}_2, \text{SO}_2 \), and \( \text{HCHO} \) (formaldehyde). The least-squares fitting procedure determines the four weighting factors for the above reference spectra in order to model the measured spectrum. From these, factor mixing ratios of 16.6 ± 0.8, 4.6 ± 0.6, 1.25 ± 0.02, and 2 ± 0.3 ppb, respectively, for the above species were derived. Further fitted parameters compensate for slight errors in the wavelength–pixel mapping. In addition a fifth-order polynomial was fitted. The remaining residual spectrum after removal of the absorption structures is shown as the bottom trace.

A section of the OH absorption spectrum, is presented in Figure 10 together with the spectra of several interfering species. It can be seen that the interference by those species can be readily eliminated, because the OH spectrum consists of several isolated groups of lines, whereas the interfering absorption features are more or less evenly distributed over the observed spectral interval. Therefore the strengths of the interfering spectra can be quite accurately measured in the gaps between the OH lines. Once the strength is known the interfering spectra are easily subtracted from the observed spectra.

7 SENSITIVITY AND DETECTION LIMITS OF DIFFERENTIAL OPTICAL ABSORPTION SPECTROSCOPY

7.1 Species Measurable by Differential Optical Absorption Spectroscopy

A summary of the species detectable by DOAS is given in Table 1 and Figure 8, which also give detection limits for typical measurement conditions. The list is constantly growing; for instance Etzkorn et al. report structured absorption spectra of 24 monocyclic aromatic species, which allow their sensitive detection by DOAS.

7.2 Detection Limits

The detection limit for a particular substance (with known differential absorption cross-section) at a given length \( L \) of the light path can be calculated according to Equation (2), by substituting the minimum detectable optical density \( D_o \) for \( D \).

The accuracy of the derived concentration values thus depends on the residual noise in the spectrum being of the order of the minimum detectable optical density \( D_o \) as well as on the error in \( \sigma(\lambda) \). Typical uncertainties of \( \sigma(\lambda) \) are in the 1–10% range. At concentrations close to the detection limit the former source of error will dominate, whereas at high concentrations the accuracy is determined by \( \sigma(\lambda) \). Additional work still needs to be done on the issue of optimum filtering of DOAS spectra.

In general \( D_o \) is determined from photoelectron statistics (shot noise), which is a function of light intensity, and residual absorption structures, denoted here as \( B \) and being of the order of \( 10^{-4} \) for a typical DOAS system. Photoelectron shot noise is proportional to \( N^{-1/2} \), where \( N \) is the total number of photons recorded around the
center of the absorption line during the time interval \( t \) of the measurement (Equation 11).

\[
D_o = (1/N + B^2)^{1/2}
\]

(11)

If sufficient light is available, \( D_o \) is limited by \( B \). For DOAS systems using artificial light sources in typical situations an integration time of the order of seconds (for solid-state multichannel detectors) to minutes (for optomechanical detection) should be sufficient. ZSL/DOAS systems require from below 1 min to 10 min integration time, depending on the SZA.

Although for a given minimum detectable optical density the detection limit improves proportionally to the length of the light path, the actual detection limit will not always improve with a longer light path. This is because with a longer light path the received light intensity \( I_o \) is reduced, leading to increased photoelectron shot noise associated with the measurements of \( I(\lambda) \) and thus increasing the minimum detectable optical density.

For a typical DOAS system there are no geometrical light losses up to pathlengths of about 2 km (for longer light paths, the size of the light source mirror could be increased). However, in addition to geometrical light losses, light attenuation due to atmospheric absorption as well as to scattering affect the magnitude of the received light signal (Equation 12):

\[
I_{\text{received}} = I_{\text{source}} \exp(-L/L_o)
\]

(12)

where the absorption length \( L_o \) reflects the combined effects of broad band atmospheric absorption, MS and RS. The noise level of the detector is essentially dependent on the number of photons received and thus is proportional to the square root of the intensity. The signal-to-noise ratio of a DOAS system as a function of the light pathlength \( L \) can be expressed (Equation 13) as

\[
\frac{D'}{N} \approx LG(\lambda) \exp \left( -\frac{L}{2L_o} \right)
\]

(13)

where \( G(\lambda) \) varies from a constant at very short light paths \( L \) to \( G(\lambda) = L^{-1} \) (intermediate \( L \)), to \( G(\lambda) = L^{-2} \) (at very large \( L \)). Equation (13) yields optimum \( D'/N \) ratios for light pathlengths of \( L = 2L_o \) (small \( L \)), \( L = L_o \) (intermediate \( L \)), or a boundary maximum at the shortest light path (very large \( L \)). Although there are no lower limits for \( L_o \) in the atmosphere (fog), the upper limits are given by RS, and the scattering by atmospheric background aerosol which indicate optimum light pathlengths (2\( L_o \)) in excess of 10 km for wavelengths above 300 nm.

Another point to consider is the width \( \Gamma \) of the absorption line (or band). At a given spectral intensity of the light source \( N(\lambda) \) the light intensity around the line center will be \( N(\lambda) d\lambda \approx N(\lambda) \Gamma \) (in photons per nanometer and second), thus the detection of a spectrally narrow absorption line requires a proportionally higher spectral intensity of the light source (section 4.1.1).

For a given spectrometer the light throughput varies in proportion the square of the spectral resolution (here expressed as the half-width of the instrument function \( \Gamma_o \)), thus the light intensity at the output becomes \( I \approx I_o/\Gamma_o^2 \).

The signal in the spectrum is the differential optical density \( D' \), which is (for a given species, wavelength, and light path) proportional to the concentration and is also a function of the spectral resolution (Figure 11). In the case of shot noise limitation (see above) \( D_o \) in the spectrum is inversely proportional to the square root of \( I \), thus in general the signal as a function of the spectral resolution will vary proportionally to \( \sigma(R) \) as a function of resolution. Frequently \( \sigma(\Gamma_o) \) can be approximated as a linear function \( \sigma'(\Gamma_o) \approx f(\Gamma_o) \approx \sigma_o(1 - a\Gamma_o) \). Where \( a \) is a constant (\( a \approx 1 \text{ nm}^{-1} \)). In this case the optimum \( D'/N \) is thus obtained at the resolution \( \Gamma_{\text{opt}} = 1/2a \).

![Figure 11 NO2 spectra at different resolution for the same NO2 column density. Traces from top to bottom: 0.01 nm, 0.3 nm, 1.0 nm, and 3.0 nm resolution. The apparent absorption cross-section decreases by almost one order of magnitude, when the spectral resolution is reduced from 0.3 to 3 nm.](image)
ENVIRONMENT: TRACE GAS MONITORING

7.3 Airmass Factors for Scattered Light Operation

The slant column density (SCD) is an average of the column densities seen by many nearly horizontal rays (at SZA = 90°) traversing the atmosphere at long paths and then being scattered in the zenith, see Figure 12(a) and (b) (In view of the origin of the absorption the term apparent column density (ACD) would describe the situation better.) Interpretation of the SCD (slant column density) ACD, therefore, requires radiation transport modeling.\(^{15,19,88,89}\) The results of those calculations are usually expressed as the AMF, which describes the ratio of the SCD to the VCD of the trace species. For medium and small SZAs, i.e. \(\theta \leq 70^\circ\), the AMF can be approximated by \(1/\cos(\theta)\). At \(\theta = 90^\circ\) (sunset or sunrise) the AMF typically reaches a value of about 20 for a stratospheric species near 25 km, but the actual value can vary widely as a function of wavelength, vertical trace gas profile, and stratospheric aerosol loading.\(^{15,88,90}\)

8 APPLICATIONS OF DIFFERENTIAL OPTICAL ABSORPTION SPECTROSCOPY

DOAS applications (Figures 13 and 14) encompass studies in urban air, measurements in rural areas, observations in the background troposphere, as well as investigations of the distribution of stratospheric ozone and species leading to its destruction. In addition, geometric light pathlengths in clouds or haze can be determined. The following discussion gives a few examples.

An important early result obtained with DOAS was the first unambiguous detection of nitrous acid (HONO)
in urban air. Nitrous acid is produced from NO\textsubscript{2} and water at various types of surfaces. Although many subsequent DOAS investigations confirmed that HONO levels rarely exceed 5% of the NO\textsubscript{2} it is, nevertheless, significant for atmospheric chemistry because its photolysis (Equation 14)

$$\text{HONO} + \text{hv} \rightarrow \text{OH} + \text{NO} \quad (14)$$

leads to the production of OH radicals which, in turn, initiate most chemical degradation processes of air pollutants.

The detection of OH radicals presented a major challenge for DOAS for a long time, because (daytime) atmospheric OH levels are of the order of 10\textsuperscript{6} molecules per cubic centimeter (roughly 0.04 ppt). After early attempts\textsuperscript{(45)} steady progress was made\textsuperscript{(91,92)} until excellent atmospheric spectra of OH were reported.\textsuperscript{(74)}

Another radical species, the nitrate radical (NO\textsubscript{3}) was also discovered in the stratosphere\textsuperscript{(50)} and troposphere\textsuperscript{(51,93)} by DOAS techniques. Nitrate radicals are formed via oxidation of NO\textsubscript{2} by ozone (Equation 15):

$$\text{NO}_2 + \text{O}_3 \rightarrow \text{NO}_3 + \text{O}_2 \quad (15)$$

The nitrate radical is a strong oxidant, initiating the degradation of many (unsaturated) hydrocarbons. Some the oxidation products lead to the formation of organic peroxy and HO\textsubscript{2} radicals, which in turn can yield OH radicals. As the formation of NO\textsubscript{2} does not require sunlight, this OH source is also active at night.

Among the first indications of the involvement of chlorine species in the formation of the Antarctic ozone hole was the detection of OC\textsubscript{1}O by ZSL/DOAS.\textsuperscript{(29)} Bromine monoxide (BrO) could also be detected in stratospheric air.\textsuperscript{(25,33,34,94)}

Ground-based DOAS systems with artificial light sources have also detected reactive halogen species in the troposphere, such as bromine monoxide BrO and possibly ClO.\textsuperscript{(7,95)} The distribution of stratospheric BrO\textsuperscript{(94)} and tropospheric BrO\textsuperscript{(97,98)} was mapped by satellite-borne DOAS. As in the stratosphere, halogen monoxide radicals lead to very efficient, catalytic ozone destruction. A spectacular phenomenon caused by BrO (and possibly ClO) is the complete, episodic destruction of boundary layer ozone during the polar spring (the polar tropospheric ozone hole).\textsuperscript{(7)}

By reversing the usual DOAS approach, so as to determine unknown trace gas concentrations for a known light pathlength, the average lengths of photon paths in clouds could be determined by making use of the known concentrations of oxygen (O\textsubscript{2}), tropospheric ozone, or oxygen dimers (O\textsubscript{2})\textsubscript{2} (section 3.5).\textsuperscript{(37,41)} By analyzing the absorption of individual rotational lines (e.g. of the O\textsubscript{2} a band around 765 nm) it was possible to infer not only the average light pathlength in clouds but also elements of its distribution.\textsuperscript{(42)} These data give new insights into the internal structure and properties of the radiation field inside clouds.

DIFFERENTIAL OPTICAL ABSORPTION SPECTROSCOPY, AIR MONITORING BY

Modern diode laser spectroscopy is becoming an important and a more widely used tool for detection and measurement of trace gases. The change is driven by the recent advances in diode laser technology and diode laser frequency conversion techniques, which now push the limits of emission wavelength, output power, operating temperature, miniaturization, and cost. Basic features of the diode laser now find new, interesting, and unique use in well-established laboratory and field applications related to trace-gas detection, and in some instances even transform the traditional spectroscopic methods. It is the purpose of this chapter to familiarize the reader with the key elements of diode laser technology and analytical methods used in diode laser spectroscopy.

1 INTRODUCTION

Sensors based on tuneable diode lasers have found widespread applications to the sensitive and selective detection of environmentally important atmospheric trace gases in real time. The motivation for such precise species concentration measurements of gaseous compounds in ambient air includes such diverse fields as urban (e.g. automobile traffic, air quality in large enclosed structures), industrial (e.g. fence line perimeter monitoring in the petrochemical industry, combustion sites and waste incinerators), rural (e.g. horticultural greenhouses, rice agro-ecosystems) emission studies, chemical analysis and control for manufacturing processes (e.g. HF, NH3 and HCl in semiconductor fabrication facilities and HF in aluminum smelters), biomedical sensing of physiologically important molecules (e.g. NO and CO), atmospheric chemistry (e.g. CO, CO2, CH4 and H2CO in global studies of the environment), and spacecraft habitat air-quality monitoring (1,2).

Numerous analytical instruments based on optical and nonoptical techniques have been developed in the past. In general, these instruments have some, but not all, of the desired characteristics that include: high sensitivity, selectivity, multicomponent detection capability, room temperature operation, large dynamic range, automatic operation, small size, high reliability, ease of use, and cost-effectiveness in terms of initial and maintenance costs. An ideal gas sensor technology that meets all these diverse requirements is, however, a challenging research and development task. Today’s state-of-the-art laser spectroscopy, for example, is far from being able to meet these requirements, but recent significant technological advances may change the way it is used in future applications. Areas of technology that have seen a particularly strong improvement are tuneable diode lasers, both near-infrared (NIR) and mid-infrared (MIR); novel nonlinear materials for optical frequency conversion; optical fiber and semiconductor amplifiers;
low-noise, room-temperature detectors; and advanced data acquisition and signal processing techniques.

Such new diode laser based spectroscopic sensors are beginning to provide excellent sensitivity and selectivity of an increasing number of organic and inorganic gaseous compounds in the infrared spectral region. This region consists of both the (NIR, 0.8 µm to 2 µm) that can be accessed by an increasing number of distributed feedback (DFB) telecommunications diode lasers and the (MIR, 2 µm to 20 µm) by lead-salt and antimony-based diode lasers, quantum cascade lasers, and compact sources based on difference-frequency mixing of commercially available diode and fiber lasers. Performance characteristics of several recent optical architectures of MIR gas sensors that have been developed and applied to real-world spectroscopic applications in the field and laboratory will be discussed. An effective method to increase sensitivity is to increase the effective optical path. This is possible for in situ, open path atmospheric measurements, but numerous applications require a compact extractive technique based on multipass cells (White, Herriott designs).

The NIR region is characterized by the presence of the first and second overtone and combination bands for many important gases. However, the transition strengths of the fundamental vibrational bands in the MIR are at least one to two orders of magnitude stronger, making this spectral regime the region of choice for high-sensitivity laser absorption spectroscopy. The detection sensitivity of current diode laser based gas sensors using direct absorption spectroscopy is limited by etalon fringes and laser feedback noise to $10^{-5}$ to $10^{-6}$ relative absorption. In addition to direct absorption spectroscopy, various techniques such as frequency modulation (FM), two-tone frequency modulation (TTFM) spectroscopy, balanced homodyne or balanced ratiometric detection (BRD) and cavity ring down spectroscopy (CRDS) can be utilized. Of these, only CRDS offers a means for avoiding the baseline variations caused by etalon fringes which often limit sensitivity.

2 FUNDAMENTALS OF GAS-PHASE SPECTROSCOPY

2.1 Atmospheric Trace Gases

Spectroscopic trace-gas detection is a method allowing one to compute concentration of a known gas, or gases, from a measured optical absorption spectrum of the gas mixture (in practice, a small fragment of the spectrum may be measured). The procedure requires a good quantitative knowledge of the gas absorption characteristics. This knowledge is the realm of molecular spectroscopy, a complex and highly developed subject that is outside the scope of this chapter. A few fundamental spectroscopic concepts and formulae that are directly applicable to gas detection are, however, summarized in this section.

Each atom or molecule, small or large, is uniquely characterized by a set of energy levels. Transitions between levels by absorption or emission of electromagnetic radiation result in highly specific spectroscopic features. These features allow both the identification and quantification of the molecular species, such as atmospheric trace gases. Molecules may undergo transition between electronic, vibrational, and rotational states when exposed to electromagnetic radiation, resulting in absorption spectra. These spectra consist of a number of discrete absorption lines. Each line will have a certain linewidth and shape that depend on temperature and what surrounds the molecule, so the lines may form resolved or unresolved bands (see Figure 1); some will be intense while others will be weak. Transitions between molecular rotational–vibrational (ro-vibrational) states occur in the infrared "fingerprint" region of the electromagnetic spectrum, approximately between the wavelengths of 2.5 µm and 25 µm. Often also overtone and combination-overtone ro-vibrational bands are possible with significantly lower line intensity as compared to those for fundamental vibrational bands and the corresponding wavelengths are in the 0.8 µm to 2.5 µm spectral region. Transitions between electronic states of atoms and molecules occur in the ultraviolet and visible spectral region, 200 nm to 500 nm.

All polyatomic molecules, with the exception of homonuclear diatomic molecules (e.g. N$_2$), absorb infrared radiation. The absorption changes the state of molecular rotation and vibration. An absorption spectrum therefore depends on the physical properties of the molecule such as size and shape and hence each molecule

Values computed for the following parameters:
- Fundamental: p = 100 torr; T = 298 K; Min. detectable absorbance = 2 × 10⁻³ using direct absorption.
- Overtone: Min. detectable absorbance ≥ 1 × 10⁻⁵ using either balanced detection/FM-techniques.

MDC, minimal detectable concentration.

### 2.2 Absorption Line Shape

In the absence of optical saturation and particulate-related scattering, the intensity of light I(x) propagating in a homogeneous gas follows the Beer–Lambert law (Equation 1):

$$ I(x) = I_0 \exp(-\sigma_m(v)N_m x) $$  \hspace{1cm} (1)

Here \( m \) is the gas species index that labels the molecular concentration \( N_m \) and absorption cross-section \( \sigma_m(v) \). The molecular absorption cross-section depends on frequency and has the units of cm² per molecule. It is the sum of cross-sections of all individual ro-vibrational transitions (Equation 2):

$$ \sigma_m(v) = \sum_n S_n \Gamma(v - v_n) $$  \hspace{1cm} (2)

We label the transitions using the index \( n \); thus \( v_n \) is the frequency of the \( n \)-th transition and \( S_n \) is its intensity. Technically both these quantities should also bear the index \( m \) to remind that they refer to a certain gas species, but for simplicity it is not done here.

The function \( \Gamma(v) \) describes the line shape and has the same analytical form for all transitions. In MIR spectroscopy, the broadening of an individual transition due to finite upper-level lifetime is insignificant compared to broadening by the other two important mechanisms – thermal motion and molecular collisions. Their individual and combined effects on a molecular transition at a frequency \( v_n \) are expressed as follows (Equations 3–7):

#### Thermal motion (Gaussian):

$$ \Gamma(v) = \frac{1}{\Delta v_T \sqrt{\pi}} \exp\left(-\frac{v^2}{\Delta v_T^2}\right) $$  \hspace{1cm} (3)

$$ \Delta v_T = \frac{v_n}{c} \sqrt{\frac{2kT}{M}} $$  \hspace{1cm} (4)

#### Molecular collisions (Lorentzian):

$$ \Gamma(v) = \frac{1}{\pi\gamma_n P} \left[ 1 + \left(\frac{v}{\gamma_n P}\right)^2 \right]^{-1} $$  \hspace{1cm} (5)

#### Combined broadening (Voigt):

$$ \Gamma(v) = \frac{1}{\pi\gamma_n P} V \left(\frac{v}{\gamma_n P}\right)^2 $$

$$ V(x, y) = \frac{1}{\pi} \int_{-\infty}^{+\infty} \exp(-x^2) dx $$

<table>
<thead>
<tr>
<th>( V(x, y) )</th>
<th>( \pi \int_{-\infty}^{+\infty} \exp(-x^2) dx )</th>
</tr>
</thead>
<tbody>
<tr>
<td>( x = (x + yT)^2 )</td>
<td>( 1 + (x + yT)^2 )</td>
</tr>
</tbody>
</table>

Here \( c \) is the speed of light in vacuum, \( k \) the Boltzmann’s constant, \( T \) the gas temperature, \( M \) the mass of the molecule, \( P \) the gas pressure, and \( \gamma_n \) the coefficient of pressure broadening. The quantities \( \Delta v_T \) and \( 2\gamma_n P \) are referred to as the Doppler- and pressure-broadened linewidths. The line shape that results from the combined effect of Doppler- and pressure-broadening is a convolution of the two respective line shapes. It is known...
as the Voigt profile, and its mathematical expression \( V(x, y) \) can not be further simplified. The physical significance of the convolution is that the Voigt profile has different asymptotic shapes for very low and very high gas pressure. At low pressure, molecular collisions are less frequent, leaving thermal motion the dominant broadening mechanism – the corresponding line shape is near-Gaussian. As the gas pressure increases the collisions take over, and the resulting line shape is near-Lorentzian (see Figure 2).

The previous expressions do not include the effect of pressure shift, which is typically in the range of several megahertz per atmosphere. The shift is very small compared to the width of an atmospheric-pressure-broadened line, typically several gigahertz.

It is common practice in infrared spectroscopy to express transition frequencies in inverse centimeters (cm\(^{-1}\)), or wavenumbers, defined simply as the inverse of the transition wavelength in vacuum, \( v = \lambda^{-1} \). Multiplying this quantity by \( c \) gives the frequency in Hertz; thus 1 cm\(^{-1}\) is roughly 30 GHz. We shall use both units throughout this chapter, where appropriate.

One can verify, by integrating the absorption cross-section of an individual transition over frequency, that it is independent of the broadening mechanism and is equal to the line intensity \( S_n \), in the units of cm per molecule. Line intensity is proportional to the lower-state population density of a transition and thus depends on temperature (see Figure 3).

![Figure 3 Absorption spectra of pure CO\(_2\) at a pressure of 7 mbar over a 1 cm path calculated at two different temperatures using the HITRAN database. The dotted trace has been offset for clarity and corresponds to \( T = 210\) K, simulating the surface atmosphere of Mars. The strong dependence of line intensity on temperature for the transitions P44 and P45 should be noted.](image)

To a good approximation, especially at low temperatures, the sum of line intensities of all transitions in a band is independent of temperature and is known as the band strength \( B_m \) (Equation 8):

\[
B_m = \int_{-\infty}^{+\infty} \sigma_m(v) \, dv = \sum_n S_n
\]

It contains information on the vibrational electric dipole moment. Thus in order to compute the absorption cross-section \( \sigma_m(v) \) at any frequency, one must know the values \( v_n \), \( S_n \), and \( \gamma_n \) for all transitions. These parameters have been measured and calculated for many lightweight gas molecules across the microwave and infrared spectrum, and compiled into extensive databases such as HITRAN and GEISA. Numerically accurate absorption spectra can be computed based on these data, not only for single gas species but for gas mixtures as well.

### 2.3 Spectra of Multicomponent Gas Mixtures

Analytical formulae given in the preceding section apply also to gas mixtures. The total absorption cross-section \( \sigma(v) \) is then a weighted average of absorption cross-sections of individual species, with the mole fraction \( C_m \) of each species used as the weight coefficient (Equations 9 and 10):

\[
\sigma(v) = \sum_m C_m \sigma_m(v)
\]

\[
\sum_m C_m = 1
\]

For each of the \( m \) species, the pressure broadening coefficients \( \gamma_n \) generally depend on the transition. They also

![Figure 2 Frequency-dependent absorption cross-section of the R(6) fundamental transition of carbon monoxide at room temperature, plotted for different values of background air pressure. The horizontal axis is in cm\(^{-1}\) relative to the line center, \( \nu_{R6} = 2169.2\) cm\(^{-1}\). Area under each curve, or line intensity, is the same: \( S = 4.44 \times 10^{-19}\) cm. At 40 torr background air pressure, the Doppler- and collision-broadened linewidths are approximately equal: 0.003 cm\(^{-1}\).](image)
depend on the type of molecule with which the collisions occur. In general, partial pressures in conjunction with the appropriate pressure-broadening coefficients should be used to compute the overall pressure broadening from all gases present in the background (this includes self-broadening). Air-broadening coefficients are particularly useful in calculations, and are listed in spectroscopic databases\(^{(4,5)}\).

In trace-gas sensing applications, however, the species of interest are often present in very low concentrations, so that self-broadening and broadening against other trace gases can be neglected in calculations, and air-broadening alone will suffice. For the conditions of atmospheric pressure broadening, \(\gamma P \gg \Delta v_T\), the Doppler contribution to the overall linewidth can often be neglected, and the line shape be treated as pure Lorentzian. Likewise, at pressures low enough to ensure \(\gamma P \ll \Delta v_T\), the line shape can be treated as pure Gaussian. In either case, calculation of the line profile is simplified considerably.

At intermediate total pressures, \(\gamma P \sim \Delta v_T\), which for most lightweight gases range from 5 to 100 torr, calculation of the Voigt profile is necessary to obtain numerically accurate absorption spectra. Methods for approximate calculation of the Voigt profile, and the related plasma dispersion function, are now a well-developed subject. We have found the approximations published by Humlicek\(^{(13)}\) to be particularly useful.

### 3 Laser Spectroscopic Sources

#### 3.1 Advantages of Diode Lasers

Soon after the first semiconductor (diode) laser was developed in 1962, diode laser spectroscopy became a firmly entrenched technique for detection, identification, and measurement of molecular and atomic species in the gas phase. The reason for its wide acceptance in the scientific community was twofold. First, narrow-linewidth light sources such as lasers were well suited for probing the inherently narrow molecular and atomic transitions, so that both the line shape and intensity could be measured accurately and rapidly. Lasers simply offered better wavelength resolution (linewidth) and spectral brightness (power emitted per unit linewidth) than conventional grating or prism monochromators. Second, among all lasers, diode lasers offered a unique combination of tuneability, output power, small size, and modulation capabilities (see Table 2). In other words they are significantly more convenient to use than other sources. Perhaps the most important advantages of diode lasers are the simple excitation in the form of electric current and the fact that the laser wavelength and output power depend on the current. For small changes in the injection current, that dependence is nearly linear and instantaneous, allowing predictable and fast wavelength control. This advantage is discussed in section 4.3.

Diode laser spectroscopy is divided into two categories according to the spectral region used. MIR spectroscopy is used in the “fingerprint” region from 2.5 \(\mu\)m to 25 \(\mu\)m where most molecular species exhibit fundamental absorption. It offers the highest detection sensitivity among spectroscopic methods, primarily because the fundamental absorption bands are very strong. Diode lasers operating at MIR wavelengths typically deliver 100-\(\mu\)W output power and require cryogenic cooling (more on this in section 3.3). NIR, or “overtone”, spectroscopy employs room-temperature diode lasers at wavelengths below 2\(\mu\)m. Detected here are the short-wavelength molecular overtone transitions that are typically a factor of 30 to 300 weaker than the fundamental transitions. The two types of molecular spectroscopy just described represent the two different choices made in the tradeoff between absorption strength and the optical power available to detect it. MIR spectroscopy is used whenever higher sensitivity is needed, but at the expense of cryogenic cooling. Overtone spectroscopy is the method of choice in applications where lower sensitivity can be tolerated, but where low cost, reliability, and room-temperature operation are paramount. Alternative techniques for the generation of MIR light for spectroscopic applications will be discussed in section 3.4.

#### 3.2 Overtone Band Detection with Near-infrared Diode Lasers

NIR spectrometers usually employ commercial diode lasers with emission wavelengths from 780 nm to 1900 nm. Gas detection at these wavelengths is based on the molecular vibration overtone and combination-overtone bands that are significantly less intense than the fundamental

bands. For example, the lines of the first overtone stretch vibration band of methane centered at 1.6 μm is roughly 160 times weaker than the fundamental band. Thus ambient methane would cause a 0.005% absorption over a 1-m path length at this wavelength at room temperature. Reliable measurement of such low absorption is difficult even under laboratory conditions, so longer path lengths or special measurement techniques are necessary to render a satisfactory signal-to-noise ratio for applications requiring trace-level monitoring.

Overtone spectrometers usually have plenty of optical probe power to deal with this problem. NIR diode lasers emit anywhere from 1 to 100 mW of single-frequency radiation with low excess noise: 15 to 35 dB over shot noise limit is typical, and it can be detected with a silicon photo-diode. They are fast, with modulation bandwidths of over a gigahertz allowing rapid scanning, fast FM, and leading to gas detection in real time.

High output power levels have two important benefits. First, detector noise can be neglected and the measurement of absorption be performed near the optical shot-noise limit. For example, Allen et al. report a detection sensitivity of $2 \times 10^{-7}$ Hz$^{-1/2}$ absorption units with the use of a 1.3-μm diode laser and a balanced ratio-metric detector. Second, with high initial power available in a beam, one can employ a multi-pass cell to propagate the beam back and forth through a gas sample, achieving long effective path lengths and thus increasing the observed absorption signal. Although the throughput of such a cell decreases exponentially as the number of passes increases (also see section 4.1), there is still plenty of light left at the end to permit measurements that are not limited by detector noise.

NIR overtone spectrometers, such as one developed by Uehara and Tai, are usually built to detect one or a few specific gases, for two reasons. First, the NIR wavelength region from 780 to 1900 nm is not covered completely; diode lasers are available at only few discrete wavelengths, and each has a limited tuning range when operated without an external cavity. Second, these devices are relatively inexpensive – sometimes under $50 in small quantities – making it economical to have several dedicated lasers, each detecting one gas species, in a single instrument. This configuration is also attractive because different gas species can be measured in parallel. For example, several groups have developed a gas sensor that can do this using one common beam path through the sample and one detector.

Alternatively, a single external-cavity diode laser (ECDL) with a large tuning range can be used. In an ECDL, one or both faces of the laser chip are anti-reflection-coated to eliminate optical feedback. The feedback is provided by a larger, external cavity. The cavity acts as a wavelength selector, picking a specific wavelength out of the usually broad gain spectrum of the semiconductor laser material. Several cavity configurations have been developed that differ in the method of tuning, component count, output beam characteristics, and output coupling efficiency. Figure 4 shows a frequently used external cavity type, known as the Littman configuration. It employs a diffraction grating as a wavelength discriminator. The first-order diffracted beam is folded back into the cavity by a mirror that acts as a tuning element – its angle and position determine the output wavelength. The grating also functions as an output coupler, producing the zero-order (reflected) beam whose angle and point of origin are independent of wavelength. Mode-hop-free single frequency tuning ranges of over 1000 GHz have been demonstrated for an ECDL. A spectrometer based on such a widely tunable laser is a very useful tool in that it can acquire spectra of an entire molecular band in a single electronically controlled scan in a matter of seconds. Oh and Hovde, for example, used a widely tuneable 1.5-μm ECDL to record a spectrum of the $v_1 + v_3$ stretch-vibration combination band of acetylene.

NIR diode lasers often come in compact sealed packages that include a convenient fiber-coupled output. Thus the probe light can be delivered from a single source to several sampling locations. Likewise, the radiation passing through the sample can be returned to a detector via a fiber, sometimes even the same fiber (see Figure 5).

A general problem that is faced is interference by water vapor. Long path lengths do not help here as they increase not only the signal of interest but the interfering absorption as well. Multicomponent spectral
fitting algorithms have been developed that can resolve weak absorption lines of interest in the presence of heavy interference by a known gas. The problem becomes far more severe, however, when the identity of the interfering species is unknown.

### 3.3 Fundamental Band Detection with Lead-salt Diode Lasers

Lead-salt diode lasers have been developed for operation at wavelengths from 3 to 30 µm. They typically deliver 10–500 µW of output power in a near-diffraction-limited beam and can be tuned by temperature or current control. These lasers are based on PbS, PbSe, or PbTe semiconductors and generally require cooling near the temperature of liquid nitrogen, although recently a continuous wave (CW) operation has been achieved at temperatures as high as 195 K.\(^{20}\)

MIR spectrometers employing lead-salt diode lasers have shown perhaps the most impressive performance to date in terms of minimum detectable gas concentration. There are four reasons for this. First is the very high absorption strength of the fundamental molecular vibrational bands. For example, carbon dioxide at a 3.3 ppm concentration in air (which is roughly 100 times lower than its typical ambient level) will cause absorption of 15% at 4.23 µm over a 1 m path. Such macroscopic absorption signals can be easily measured even without sophisticated signal processing techniques. Second, lead-salt diode laser spectrometers use cryogenically cooled InSb or HgCdTe detectors with noise-equivalent powers in the range of 0.5 to 50 pW Hz\(^{-1/2}\), and although the lead-salt lasers produce less output power than their NIR counterparts, there is still enough light to render the detector noise virtually nonexistent and allow shot-noise-limited detection. Third, near-diffraction-limited beam characteristics of lead-salt diode lasers allow beam shaping and propagation over long distances; this makes it possible to use multipass cells or remote sampling in open air. Fourth, lead-salt diode lasers have FM capabilities similar to those of NIR diode lasers, allowing the use of harmonic detection and two-tone modulation techniques—efficient methods of noise bandwidth reduction, to be discussed in section 4.3.

These advantages add up to a real-world instrument performance that is impressive.\(^{21}\) Schiff et al.\(^{22}\) report the detection limit 75 ppt for airborne measurements of HNO\(_3\) in the continental boundary layer with a response time of 3 minutes. Werle and company\(^{23}\) achieved a detection limit of 10 ppt for NO\(_2\) under laboratory conditions using a signal averaging time of 25 s.

Although well entrenched in a spectroscopic laboratory, lead-salt diode lasers are seldom used in industrial applications. Preventing their wide acceptance are several important practical drawbacks. Perhaps the most serious one is the large manufacturing spread of operating wavelengths. The situation is aggravated by the fact that each individual laser has a rather limited tuning range, typically 100 cm\(^{-1}\) with temperature control, and that the range itself is not free of mode hops. This makes it difficult to find a laser chip that actually tunes to a specific wavelength—a situation potentially catastrophic in applications where there is a limited choice of absorption lines free from interference by other lines, e.g. detection of formaldehyde.\(^{24}\)

A more subtle problem with lead-salt diode lasers has to do with thermal cycling, a process in which a laser is simply warmed up to room temperature and then cooled back to its normal operating temperature. The simple process tends to cause irreversible changes in prior laser tuning characteristics and emission wavelength.

Despite these and other technical difficulties, several specialized trace-gas sensors based on lead-salt diode lasers have been developed for field use. These instruments show excellent performance, proving just how effective the use of a MIR diode laser can be. For example, Webster et al.\(^{25}\) reported the design and operation of a fully automatic, compact sensor for the measurement of five trace gases in the lower stratosphere on board an airplane. Their instrument houses four lasers and four detectors mounted on the same liquid-nitrogen-cooled platform, beam shaping optics, a compact multipass absorption cell with 80 m path length, analog electronics, and a computer-controlled data storage system. It is capable of detecting optical absorption as small as 10\(^{-5}\) which corresponds to detection limits in the range of several tens of ppt for species such as HCl, NO\(_2\), HNO\(_3\), CH\(_4\), and N\(_2\)O. Podolske and Loewenstein\(^{26}\) report construction and performance of a similar instrument that uses an additional, “zero”, beam for removing the background.

**Figure 5** Schematic of a NIR diode laser spectrometer using a single fiber to deliver the light to and from the sampling location. The reference detector monitors the laser output power during frequency scans. The optical circulator transmits light from port 1 to 2 and from 2 to 3, and is used to route the returned beam to the signal detector.
absorption signal caused by gases within the instrument case. Both instruments employ wavelength modulation (WM) and second harmonic detection to achieve high sensitivity.

3.4 Diode Laser Frequency Conversion

A more recent technique for producing spectroscopic MIR light is laser difference-frequency generation (DFG). Two laser beams at different frequencies combined in a nonlinear material with suitable dispersion characteristics can generate a beam at the difference-frequency (“idler”). Narrow emission spectra of the two lasers, usually referred to as “pump” and “signal”, translate into a similarly narrow spectrum of the idler wave. Idler wavelength tuning is accomplished by tuning of the pump laser, or signal laser, or both (see Figure 6).

In the early demonstration of this method by Pine, an argon-ion laser output and a dye laser output were combined in bulk lithium niobate to produce a narrow-band (15 MHz), 2.2–4.2 μm tuneable radiation. However, NIR diode lasers can now be used instead, making it feasible to construct compact MIR spectrometers that operate at room temperature (see Figure 7). Thus the convenience and practicality of NIR diode laser technology are combined with analytical power of MIR spectroscopy in a single instrument. Such an instrument inherits the single-frequency operation and high speed modulation capabilities of diode lasers, and takes advantage of their relatively wide tuning range. For example, a typical 780-nm diode laser (see Table 2) can be tuned over 20 nm, or 2.6% in wavelength, by temperature control without appreciable change in output power. When the output of such a laser is down-converted by mixing with a 980 nm diode laser, the tuning range in frequency units remains the same, in this case a very significant tuning range: 3.6–4.1 μm, or 13% in wavelength.

The practicality of diode-pumped MIR frequency conversion received a significant boost from the development of novel nonlinear materials, such as periodically poled lithium niobate (LiNbO₃), lithium tantalate (LiTaO₃), and potassium titanyl phosphate (KTiOPo₄, or KTP) at wavelengths in the 2.5–5.2 μm spectral region. Quasi-phase matching properties of each of these crystals can be engineered for interaction of any pump and signal wavelengths within transparency range of the crystal, allowing significant flexibility in the choice of laser sources. Although routinely used for spectroscopy and gas detection, the DFG in bulk nonlinear crystals is characterized by low conversion efficiency, typically in the range of 0.002–0.05% W⁻¹ cm⁻¹. A detailed quantitative theory of this nonlinear optical process, developed by Boyd and Kleinman, is beyond the scope of this review chapter, so we will state simply that the maximum idler power generated in a given crystal is proportional to the product of crystal length, pump power, signal power, and the squared second-order nonlinear coefficient of the crystal. Maximum DFG output power is achieved by means of optimal focusing, for which any further increase in beam intensity through tighter focusing is offset by a decrease in interaction length due to diffraction, resulting in no gain in output power. For DFG radiation longer than 5 μm it is possible to use birefringent bulk

![Figure 6](image-url)

**Figure 6** Schematic of difference-frequency spectrometer. A free-running Fabry–Perot diode laser at 808 nm, the “pump”, is mixed with a diode-pumped Nd:YAG laser, the “signal”, in a periodically poled LiNbO₃ (PPLN) crystal to produce a 3.4-μm tuneable radiation. An antireflection-coated germanium filter blocks the residual pump and signal light.
Figure 7 Portable diode-pumped difference-frequency spectrometer for detection of trace gases. DBR: distributed Bragg reflector.

nonlinear optical materials, such as AgGaS$_2$, AgGaSe$_2$, GaSe and in the future, quasi-phase matched GaAs.

The tradeoff between beam size and interaction length can be eliminated altogether in guided-wave DFG. Tight optical confinement of pump and signal radiation near the waveguide core creates a region of high intensity and good modal overlap which are both maintained throughout, and independent of, the length of the waveguide. Interaction length is now limited by the length of the waveguide, not diffraction. Guided-wave parametric processes, such as OPO, SHG, and DFG, have been demonstrated in periodically poled LiNbO$_3$, LiTaO$_3$, and KTP. In LiNbO$_3$, for example, a waveguide can be formed by titanium in-diffusion, or a $^{+}\text{Li}\leftrightarrow ^{+}\text{H}$ ion exchange. The latter process is normally followed by several hours of annealing at elevated temperature to create a graded index distribution.

A DFG waveguide designed to carry a single spatial mode at the idler wavelength is necessarily multimode at the shorter, pump and signal wavelengths. The presence of multiple spatial modes complicates the waveguide phase matching characteristics considerably. For example, a TM$_{00}$ (fundamental) mode at the signal wavelength will interact with TM$_{02}$ and TM$_{10}$ modes at the pump wavelength, but not with TM$_{01}$ or TM$_{11}$ modes. Efficient and reproducible fundamental-mode excitation of a DFG waveguide was first achieved by Chou et al. who used a combination of a mode filter and an adiabatic taper (see Figure 8). An improved device featuring separate inputs for the pump and signal beams followed by a directional coupler has also been demonstrated. DFG waveguides have been used to build viable sources of MIR radiation for spectroscopic purposes.

Figure 8 Alternative geometries of a tapered waveguide for difference-frequency mixing. Shaded regions indicate material with higher index of refraction. Laser light is launched into the mode filter that carries a single (fundamental) spatial mode. The mode size is then adiabatically converted to fit the mixing waveguide which is multimode. Periodic segmentation of the waveguide acts to reduce the effective index. It also provides independent control of the effective waveguide width and depth.

4 TECHNIQUES FOR THE MEASUREMENT OF SMALL GAS CONCENTRATIONS

4.1 Long Path Length and Cavity-enhanced Spectroscopy

Gas sensors often deal with gas concentration and sample size so small that the detected full-scale absorption signal is indistinguishable from system noise. This is
no surprise, since most photons in the probe beam pass through the sample without being absorbed. If one were able to somehow “recycle” these unabsorbed photons, by forcing them to pass through the sample many times, one would obtain better contrast between signals on and off resonance of the molecular transition. Two different forms of this idea have been developed to date.

Long-path length spectroscopy, not to be confused with remote sensing or fence-line monitoring, refers to the use of an optical set-up that provides multiple passes of the probe beam through a relatively small sample volume. An example is the Herriott cell, a device with two identical spherical mirrors facing each other and separated by nearly their radius of curvature (see Figure 9). A probe beam launched through a hole in one of the mirrors at an angle to the optical axis, completes a certain number of passes between the mirrors, and exits through the same hole. The mirror curvature, applied to the beam at each reflection, keeps it from diverging, as if in a cavity. The beam bounce pattern and path length can be controlled by adjusting the mirror separation. The picture is deceptively simple, but certain design rules must be followed to ensure that the beam exit the cell after a controlled number of passes, especially in the case of astigmatic mirrors. The number of passes can routinely exceed 100, thus providing a commensurate improvement in signal strength (see Figure 10). It is important to recognize that mirrors are not perfect, and a small portion of the probe light is lost to absorption and scattering each time the beam bounces. Optical throughput of the cell thus decreases exponentially with the number of passes, whereas the detected peak-to-peak absorption only increases linearly (in the small-signal limit) with the number of passes.

Several configurations of the multipass cell are available that offer different mirror counts, input and output ports, and beam patterns. They can be sealed, for the measurement in static gas samples or controlled gas flows, or open to ambient air. Performance of long path length multipass cells, especially those with dense beam patterns, suffers from optical interference (“fringes”) due to light scattering by the cell mirrors. The fringe magnitude is
sensitive to optical alignment and is typically on the order of 0.01–0.1% full-scale transmission (see Figure 10). Mirror drift and vibration can also become a problem, as they modulate the cell transmission. Mirror vibration, on the other hand, reduces the effective magnitude of interference fringes, as it scrambles the phase of optical feedback within the cell.

Cavity-enhanced spectroscopy is another method to increase the magnitude of absorption signal when only a small gas sample is available. Although its implementation and treatment are different from those described above for the multipass cell, the similarity is evident if one considers the idea of “recycling” photons in the probe beam. In this method, a weakly absorbing gas sample is placed inside a cavity, and the cavity is tuned to resonance with the probe beam, e.g. by a piezo-driven cavity mirror. At the peak of resonance, the cavity photon lifetime significantly exceeds the cavity round-trip time, thus increasing the probability of interaction with gas molecules in the sample. The effective number of passes between cavity mirrors, \( N \), constitutes the improvement in the magnitude of absorption signal and is proportional to cavity finesse, \( F \), which can be made rather high Equation (11):\(^{43}\)

\[ N = 2F/\pi \]  

This approximation is good for weak absorption signals. A point to consider here is that increased gas absorption acts to reduce (“spoil”) the cavity finesse. This leads to nonlinear distortion of the observed molecular line shapes, making a quantitative measurement difficult. Another point to consider is that the cavity must be kept in resonance with the probe beam when the wavelength is tuned. A feedback loop is often used, which adjusts cavity length to track the changes in probe wavelength.\(^{44}\) The rate of this electromechanical adjustment is much too slow to keep up with the laser tuning rate normally used for sensitive spectroscopy (more on this in section 4.3). Another form of cavity-enhanced spectroscopy is CRDS.\(^ {45-48}\)

An interesting, and remarkably simple, method to increase effective path length through a gas sample has recently been demonstrated by Tranchar et al.\(^ {49}\) It involves the use of a broadband integrating sphere whose inside walls diffuse light rather than reflect it. Effective path length for the probe beam inside the sphere is then given by Equation (12):

\[ L_{\text{eff}} = \frac{4R}{3(1-\rho)} \]  

Here \( R \) is the sphere radius, and \( \rho \) the diffuse reflection coefficient. Highly reflective walls (\( \rho \to 1 \)) make it impossible to obtain several meters of effective path length from a sphere as small as 10 cm in diameter. This method does not require sophisticated alignment of the probe beam into the sphere, but has the disadvantage of low detected power that is proportional to the ratio of the detector active area to the inside surface area of the sphere.

4.2 Balanced and Balanced-ratiometric Detection

Laser intensity noise and drift may limit the sensitivity with which absorption signals are measured. This is particularly true for gas lasers, or externally pumped solid-state ring lasers, where output power fluctuations induced by acoustic vibration and variations in pump power can exceed 1% full scale. Balanced detection may be used to recover small absorption signals in this situation. Noise detected in an equal-intensity replica of the probe beam, such as that created by a variable-ratio beamsplitter, is subtracted from noise detected in the probe beam, thus leaving only the uncompensated weak absorption signals of interest. A variable-ratio beamsplitter can be made by placing a polarization rotator (a half-wave plate) in series with a polarizing beamsplitter cube, as shown in Figure 11.

With the input polarization rotated about 45°, the beams emerging from the beamsplitter cube carry equal amounts of power \( P \), and power noise \( \Delta P \). In the absence of absorption, the photo-currents generated by the (identical) signal and reference detectors can be subtracted to cancel each other exactly. If one of the beams is attenuated due to small absorption \( a \), by a gas, for example, the balance of photo-currents is disturbed, and a signal is seen at the output of the amplifier (Equation 13):

\[ V_{\text{out}} = R(I_{\text{ref}} - I_{\text{sig}}) = aRS + aR\Delta P \]  

Here \( R \) is feedback resistance, and \( S \) is the detector element response, in amperes per watt. The second term constitutes noise, and the corresponding signal-to-noise ratio is \( P/\Delta P \), independent of absorption \( a \) and limited basically by the quality of the probe beam. With the use of a single detector (no balancing), the signal-to-noise ratio would be a mere \( aP/\Delta P \), i.e. absorption on the order of \( a_{\text{min}} = \Delta P/P \) would be indistinguishable from noise. In practice, adjustment of the beam splitting ratio (“zeroing”) is necessary to compensate for unequal response of the signal and reference detectors and difference in optical transmission of the signal and reference arms. Moreover, detectors must be sufficiently quiet to resolve fluctuations in probe power, and have equal delay times.

An advanced implementation of this method, proposed by Hobbs\(^ {50}\) and known as balanced ratiometric detection (BRD), uses circuitry to compute a log ratio of photo-currents, rather than their difference, and to cancel noise currents at the same time. The analog divider, whose simplified schematic is shown in Figure 12, uses
In the simple balanced detection method, a variable-ratio beamsplitter (a combination of a half-wave plate and a polarizing beamsplitter) is used to send nearly equal amounts of optical power to the signal and reference detectors, bringing $V_{\text{out}}$ to zero. The balance at the current-summing junction $X$ is maintained despite the laser amplitude noise, since the generated noise photo-currents are of opposite sign and nearly equal magnitude. An imbalance of photo-currents due to absorption in the signal beam results in a nonzero output.

![Circuit diagram of a balanced ratiometric detector.](image)

Figure 12 Circuit diagram of a balanced ratiometric detector. When currents at the summing junction $X$ are balanced, the output of the error amplifier $A_1$ is zero, and the output of the integrator $A_2$ is proportional to $\ln(I_{\text{ref}}/I_{\text{sig}} - 1)$. A nearly perfect cancellation of noise photo-currents is achieved when $I_{\text{ref}} \approx 2I_{\text{sig}}$.

logarithmic conformance and tight symmetry of base-emitter curves of a matched transistor pair. The summing junction $X$ is held at ground by an error amplifier $A_1$ whose output is integrated and applied to the base of transistor $Q_2$. When currents at the summing junction are balanced, the output of $A_1$ is zero, and the output of $A_2$ is given by Equation (14):

$$V_{\text{out}} = \left( \frac{R_2}{R_1} + \frac{1}{R_1} \right) \frac{k_B T}{e} \ln \left( \frac{I_{\text{ref}}}{I_{\text{sig}}} - 1 \right)$$

Here $k_B$ is the Boltzmann’s constant, $T$ the absolute temperature of the matched transistor pair $Q_1Q_2$, and $e$ the electron charge. This scheme provides nearly perfect cancellation of noise currents when the reference beam carries roughly twice the power of the signal beam. The signal-to-noise ratio is thus increased well beyond the $P/\Delta P$ limit of the simple balancing scheme described above.

Since the signal versus reference current balancing is performed by means of electronic feedback, no physical adjustment of the beam splitting ratio is necessary. The BRD differential response to absorption signals is nonlinear, however, in that it depends on the ratio of the signal and reference currents which changes when the signal beam is partially absorbed. It also depends on temperature in the same way the transistor base-emitter voltage does, and additional compensation circuitry is needed to produce a useful output voltage $V_{\text{out}}$. Nevertheless, detection sensitivities presently achieved with BRD are quite stunning. Noise-equivalent absorbances as low as $2 \times 10^{-7}$ Hz$^{-1/2}$ have been demonstrated by Allen et al.,$^{15}$ close to the limit imposed by the laser shot noise.

4.3 Frequency and Wavelength Modulation Spectroscopy

The ability of a diode laser to change its emission wavelength with injection current, and to do so very rapidly, is one of the reasons why the diode laser has been so effective in spectroscopic applications. The wavelength change is driven by two effects. Current-induced heating of the semiconductor junction leads to change in optical length of the laser cavity and red-shifts the laser’s broad gain curve; this constitutes “coarse” tuning. The current...
also controls the carrier density which in turn affects
the cavity refractive index; this “fine” tuning mechanism
is normally at least ten times less pronounced at low
frequencies, but becomes dominant at high frequencies
(>1 MHz). The tuning response thus depends on the
modulation rate and ranges from 2–3 GHz mAmA⁻¹ at low
frequencies to under 300 MHz mAmA⁻¹ at high frequencies.
FM is always accompanied by amplitude modulation, as
the injection current also controls the laser output power
(Equation 15):

\[ E(t) = A[1 + m \cos(\Omega t)] \sin[w t + \beta \cos(\Omega t + \Phi)] \]  (15)

Here \( E(t) \) is the laser electric field, \( w = 2\pi c/\lambda \) the laser
frequency, and \( \Omega \) the modulation frequency. By analogy
with radio communication, \( w \) is the “carrier” frequency.
The quantities \( m \) and \( \beta \) are the amplitude and FM indices,
respectively, and \( \Phi \) is the generally nonzero phase shift.
Sine-wave modulation of the diode laser has the effect
of creating multiple side bands in its otherwise nearly
monochromatic emission spectrum. Each side band is
separated from the carrier by an integer multiple of
the modulation frequency \( \Omega \), and its relative intensity
depends on \( \beta \).\(^{51}\)

In FM spectroscopy, for example, \( \Omega \) significantly
exceeds the laser linewidth that is typically several tens
of megahertz (see Table 2), and \( m, \beta \) are both small, so
that only the two first-order side bands, \( w + \Omega \) and \( w - \Omega \),
have appreciable magnitude. After uniform attenuation,
such as that encountered in nonresonant optical systems
or media (e.g. imaging optics or vacuum), the side bands
add up coherently with the carrier and balance each other
to produce a beam of nearly constant intensity, \( A² \). If
the attenuation strongly depends on frequency, however,
as is the case with most gases, one of the side bands
may become unbalanced and lead to the appearance of
multiple harmonics of \( \Omega \) in the detected laser intensity.
The strength of absorption determines the magnitude of
these harmonics, which may be measured separately and
with high noise immunity, by using a lock-in amplifier
for example. This is usually done while the laser carrier
frequency \( w \) is scanned in the vicinity of the absorption
line of interest.

This detection technique was first applied by Bjorklund
to a CW dye laser.\(^{52}\) It proved extremely powerful and is
widely used in diode laser spectroscopy today, sometimes
in modified form such as TTFM,\(^{53}\) or amplitude
modulated phase modulation (AMPM) spectroscopy.\(^{54}\)

Wavelength modulation (WM) is really another form of
FM spectroscopy, in which case the modulation frequency
\( \Omega \) is smaller than the laser linewidth, and the modulation
indices \( m \) and \( \beta \) are both large.\(^{55}\) The aforementioned
side bands are then present to a very high order and,
by virtue of their small separation from each other,
merge into a continuous spectrum. The detection is again
performed at the first, second, or higher harmonics of \( \Omega \)
as the laser carrier frequency \( w \) is scanned in the vicinity
of a gas absorption line. WM spectroscopy dominates
applications that rely on relatively low-speed detectors,
and its sensitivity is limited by the laser amplitude \( 1/f \)
noise.

4.4 Opto-acoustic Detection

Optical power absorbed by a gas from the probe beam
leads to local heating of the gas and inevitably generates
a local pressure differential. The pressure differential
can, in principle, be detected as an acoustic pulse, some
distance away from the source in any direction. A train
of acoustic pulses at a known frequency (a “tone”)
such as that produced in a gas by a chopped beam,
for example, can be detected using a microphone and a
lock-in amplifier (see Figure 13). Since power absorbed
from the probe beam depends on wavelength, a change
in the intensity of the acoustic wave will result as the
laser wavelength is tuned. Spectroscopy based on this
principle is called opto-acoustic spectroscopy (OAS), or
photo-acoustic spectroscopy (PAS). It has one important

![Figure 13](image-url) Simplified schematic of an opto-acoustic trace-gas detection system using a resonant acoustic cell. The beam is chopped at a frequency \( f \), and a synchronous acoustic signal is detected by a microphone and a lock-in amplifier. Laser WM on and off the
gas absorption line can produce an acoustic signal in much the same way as a chopped beam that is tuned to the line center.
advantage: in the absence of an absorbing gas there is no acoustic signal at all. External acoustic noise is unimportant, as it has random phase relative to the chopper and is therefore filtered away effectively by the lock-in amplifier. At some level of scrutiny, however, one might find interfering synchronous acoustic signals, such as those generated by the slightly absorbing windows of the sample cell, etc.

Since the opto-acoustic signal is proportional to beam intensity, the method has been used primarily with high-power infrared lasers, such as CO\(_2\) and CO\(_2\). Low-power diode lasers are now being used as well, although gas cells are often built as acoustic resonators in order to increase the observed signal. Surprisingly, the WM capabilities of diode lasers have found an elegant use in OAS – periodic tuning of the laser beam on and off the line resonance is also a good way to generate an acoustic wave. The theory for WM opto-acoustic signal generation involves coupled heat transfer and the Navier–Stokes equations and is beyond the scope of this review.

5 EXAMPLES OF TRACE-GAS SENSORS

Here we will describe practical embodiments of the three types of laser spectroscopic sensors described in section 3. These are sensors based on NIR semiconductor lasers, lead-salt diode lasers, and diode laser frequency conversion. We have selected one instrument in each category as an example. These instruments have either stimulated a development of a broad range of similar sensors and related measurement techniques, or are an example of how multiple elements of the developed sensor technology function together in a complete spectroscopic instrument.

5.1 Gas Sensors Based on Near-infrared Diode Laser Overtone Spectroscopy

Intense development of gas sensors based on visible and NIR semiconductor lasers has been reported by groups in the USA, Europe, and Japan. Applications in which these sensors find increasing use are combustion diagnostics, landfill emissions monitoring, natural-gas leak detection, optical sensing of flows, and industrial process control. One of the first applications of a NIR diode laser to gas detection was reported in 1992 by Uehara and Tai. Figure 14 shows a schematic diagram of spectrometer built for the purpose of detecting methane in ambient air; it uses the same transmitter design in two remote detection schemes. The transmitter employs a 1.665-μm InGaAsP DFB diode laser developed specifically for the detection of methane in the 2ν\(_3\) stretch vibration overtone band.

Laser emission in this instrument was available from both front and rear facets of the laser chip, and was detected using InGaAs pin photodiodes. The backward beam was used to dither-lock the laser wavelength to the center of the Q(6) line of methane in a reference cell. The 3-cm-long pyrex cell contained 200 torr of methane mixed with 560 torr of air. The cell windows functioned as lenses: one collimated the laser output while the other focused it on to a reference detector. The laser injection current was modulated at a rate of \(f = 5.35\) MHz and the output of the
reference detector was processed by a double-balanced mixer to recover the amplitude of the first harmonic (1f) of the modulation frequency. Due to AM–FM cross-talk in the diode laser, the amplitude is nonzero even in the absence of absorption, therefore offset cancellation was used to produce a suitable error signal. The error signal crosses zero when the laser frequency is scanned across the center of the absorption line, and therefore can be used, upon integration, as feedback to control the laser temperature. Such a simple locking scheme was reported to stabilize the center wavelength to within 10 MHz of the absorption line. After frequency stabilization was obtained, a small-amplitude second harmonic (2f) signal was added to the laser injection current to compensate the residual 2f signal amplitude in the detected forward laser beam in the absence of absorption. Absorption caused by the presence of methane in the signal beam path was then registered as a positive 2f amplitude.

Figure 15 shows an example of instrument output in the transmission scheme, in which the second harmonic amplitude alone was recorded. The signal was caused by a 100-ppm mixture of methane in air in a 50-cm-long cell. The mixture was introduced into the cell and purged subsequently with nitrogen, resulting in zero output after two minutes. The signal-to-noise ratio in the trace corresponds to a minimum detectable CH$_4$ column density of 0.3 ppm m, achieved using a signal averaging time of 1.3 s.

In the reflection detection scheme, the registered amplitude of the second harmonic depends not only on absorption, but on the range to the scattering target and on the target reflectance (wooden boards and concrete blocks were used). The amplitude of the first harmonic is directly proportional to the received optical power; quantitative detection was thus performed by computing a ratio of the 2f and 1f amplitudes. The corresponding detection sensitivity was 50 ppm m. Although higher modulation frequencies are advantageous for noise reduction, caution must be exercised when they are used in the reflection scheme. When the beam path length from transmitter to receiver changes, the detected phases of the first and second harmonics also change. For a modulation frequency of 5.35 MHz, for example, a 3.5-m change in distance to target results in a 90° phase shift in the second-harmonic signal. The phase shift must be tracked and compensated in order to maintain maximum signal intensity.\(^{51,59–63}\)

### 5.2 Tuneable Mid-infrared Diode Laser Absorption Spectrometer

In the area of MIR spectroscopy, the airborne tuneable laser absorption spectrometer (ATLAS) developed by Podolske and Loewenstein\(^ {19}\) is an example of a self-contained field instrument. It was developed for in situ measurement of nitrous oxide and carbon monoxide in the lower stratosphere from an ER-2 high-altitude aircraft. Optical layout of the instrument is shown in Figure 16. A pressure-regulated liquid nitrogen Dewar housed two different lead-salt lasers: one operating at 2169.2 cm\(^{-1}\) for the detection of carbon monoxide, and another at 1270.2 cm\(^{-1}\) for the detection of nitrous oxide. After collimation by an off-axis parabolic mirror,
the beam passed through an adjustable iris and the diagnostics section, and was then partitioned into three beams (sample, reference, and zero) by organic pellicle beamsplitters. These have the advantage of negligible thickness, hence beam displacement, and small, 5–10%, amount of deflected light, so that most of optical power remained in the sample beam. All three beams were measured by identical detectors. InAs detectors were used for the measurement of carbon monoxide at 4.7 μm, and HgCdTe detectors were used for the measurement of NO at 8 μm.

The instrument employed a noticeably complex laser current modulation and control scheme. Up to eight signals were superimposed to determine the instantaneous laser wavelength. Two of them were generated by an on-board computer for coarse and fine adjustment of the center wavelength. An adjustable amplitude, 2-kHz sine wave was added to perform WM spectroscopy. The 1f feedback signal derived from the reference channel was also added for locking of the laser wavelength to the center of a chosen absorption line (R(6) for carbon monoxide, or P(17) for nitrous oxide). A 12.8-kHz triangle wave dither was also added to suppress the effective magnitude of optical interference fringes. Another signal, a 125-Hz triangle wave was used to perform frequency scans for display purposes during instrument set-up. For the measurement of dark detector output, each period of the waveform was preceded by a 125-μs pulse that gated off the laser injection current. Each gate pulse was immediately followed by another, adjustable compensation pulse that provided heating of the laser junction that would have occurred in the absence of the gate pulse. The use of this compensation diminished the frequency drift associated with thermal recovery of the laser junction after each gate pulse.

In addition to optics, the ATLAS included a calibration and gas flow system (see Figure 17). The gas flow system routed and conditioned the flow of both the reference gas (100 ppm CO in nitrogen or 1000 ppm N₂O in nitrogen) and the sample. Air was sampled from outside the aircraft boundary layer by means of a narrow inlet tube, into which the air was propelled by ram pressure. The air then passed through a multipass cell with a residence time of approximately 1 s. Gas pressure and temperature inside the cell were maintained approximately equal that of the reference cell. Pressure equalization was accomplished by a feedback-controlled flow of the reference gas through a frit, rather than by making it a static specimen. Gas temperatures were made equal by heating of the incoming air to 25°C; this also prevented temperature-induced alignment drift of the cell mirrors. For airborne measurements of nitrous oxide, whose typical abundance in air is approximately 300 ppb, the uncertainty of ±10% was estimated for ATLAS when using a signal averaging time of 1 s.

Apart from the systems described, the ATLAS had several electronic subsystems: laser control, analog signal processing, data acquisition, computer, and the pressure and temperature control. To fully appreciate the complexity of an actual instrument designed for field applications it is helpful to consult Fried et al. and Nelson et al.

5.3 Gas Sensors Based on Difference Frequency Generation Absorption Spectroscopy

As described in section 3.4, difference frequency mixing of near infrared CW or pulsed laser sources is another convenient technique to access the molecular “fingerprint” region. Until recently, DFG sensors used discrete optical components to generate microwatt-level CW radiation. More recently, the technologies developed for optical telecommunications – optical fiber, and rare-earth-doped fiber amplifiers – have been used in DFG sensors. This approach has improved the robustness and reliability, since it ensures permanent alignment of DFG pump channels without an increase in device complexity and cost. Lancaster et al. built a portable sensor that is tuneable from 3.25 to 4.4 μm (see Figure 7).

A 20-mW ECDL with a tuning range of 814–870 nm, and an Yb-doped fiber amplifier seeded by a 1083-nm DBR were mixed in a multi-grating, temperature-controlled PPLN crystal. A 7.2-m long fiber amplifier, pumped by a 2-W diode laser at 975 nm, produced 590 mW output power when seeded with 12 mW. All amplifier components were packaged into a 9 × 11 × 2 cm³ housing.

The pump wavelengths were combined by a low-loss fiber directional coupler. An f = 1 cm Achromat lens was used for imaging the fiber output into the PPLN crystal. A 19-mm long, 0.5-mm thick crystal was used, with broadband antireflection coatings applied to both end faces. The crystal had 8 domain grating periods,
from 22.4 to 23.1 µm in 0.1 µm increments, and was temperature-controlled in the 10–85 °C range. The DFG radiation is collimated by an $f = 5$ cm CaF$_2$ lens and the residual pump light was blocked by a germanium filter. The radiation is either focused directly on a Peltier-cooled HgCdTe detector or aligned through a compact multipass cell with an effective path length from 18 to 100 m. The data acquisition system used was similar to the one described in Topfer$^{31}$ and Lancaster,$^{70}$ and consists of a compact 16-bit analog-to-digital converter card and a notebook computer. Detector voltage was sampled at a rate of 100 kHz and processed using a 9 kHz digital low-pass filter.

Coarse frequency tuning of the Littman-cavity ECDL (Figure 4) was performed by rotation of its tuning mirror with respect to the diffraction grating. The advantage of this configuration is a beam direction and a point of origin that are independent of wavelength; this allows stable coupling into an optical fiber. Fine tuning and repetitive frequency scans of up to 25 GHz were accomplished by linear current modulation of the seed DBR diode laser at a rate of 200 Hz. The instrument linewidth of 42 ± 5 MHz was measured indirectly by spectroscopy of methane at low pressure. Figure 18 shows the individual direct absorption spectra of six species of interest for trace-gas detection that are within the 3.25–4.4 µm tuning range of the sensor, including CO$_2$, N$_2$O, H$_2$CO, HCl, NO$_2$ and CH$_4$. These spectra were taken at reduced pressure (88 torr) in a multipass cell using either calibrated gas mixtures or room air. Fitted Lorentzian line shapes were used to determine gas concentrations. Stability of instrument performance was assessed by monitoring of a methane line at 3028.751 cm$^{-1}$ for an extended time period. In this experiment a calibrated $1772.7 ± 1$ ppb mixture of CH$_4$ in air was continuously flown through the multipass cell at a pressure of 88 torr. Observed standard deviation of the measurement was 0.8% (15 ppb).

The instrument occupies a 45 x 45 cm$^2$ optical breadboard mounted in a reinforced plastic suitcase for portability and weighing 25 kg. Total power consumption is approximately 60 W. To provide a continuous gas flow through the multipass cell at a controlled pressure, a two-stage diaphragm pump was used in series with a pressure flow controller. A capacitive manometer was used to measure the gas pressure just prior to the multipass cell. For the measurement of reactive gases such as H$_2$CO, HCl and NO$_2$, the gas handling system was maintained at 40 °C.

![Figure 18](image-url)
6 CONCLUSION

Spectroscopic sources for trace-gas monitoring, based on diode lasers, find increasing use in both established and new fields, including air-quality control; atmospheric chemistry; industrial, traffic, and agricultural emissions; chemical analysis and process control; and medical diagnostics. The moderate cost, compact gas sensor using all-solid-state technology is capable of highly sensitive, selective detection and real-time analysis of a large number of gas species by means of absorption spectroscopy in the overtone and fundamental spectral regions. Reductions in cost and complexity, coupled with improved reliability and ease of operation, are now made as a result of the availability of several novel technologies developed by the telecommunications and computer industries that are equally applicable and useful in state-of-the-art gas sensors.

Fourier Transform Infrared Spectrometry in Atmospheric and Trace Gas Analysis

David W.T. Griffith and Ian M. Jamie
University of Wollongong, Wollongong, Australia

1 Introduction

Fourier transform infrared (FTIR) spectrometry is the dominant technique used to measure the infrared (IR) absorption and emission spectra of most materials, with substantial advantages in signal-to-noise ratio (S/N), resolution, speed and detection limits over conventional dispersive spectroscopy. In this application, FTIR spectrometry is used to measure the trace gas composition of the atmosphere. Applications to both clean and polluted air are described. Techniques include measurements over open paths in situ, sampling and measurement in closed cells in the field or laboratory and, briefly, remote sensing using the sun, sky or natural hot objects as an IR radiation source. The techniques are applicable to a very wide range of compounds, including labile or reactive species, and all species are measured simultaneously. Detection limits vary with the application but are typically of the order of parts per billion (ppb) or parts per trillion (ppt) in air.

1 INTRODUCTION

Atmospheric analysis by IR spectrometry began over a century ago with measurements of the solar absorption spectrum from the earth’s surface, providing the first identification of minor atmospheric gases such as nitrous oxide and carbon monoxide. The technique developed rapidly from the late 1940s and early 1950s...
using grating spectrometers. Around the same time, Stephens, Hanst and co-workers used long-path cells to study the chemistry of urban pollution, identifying for example the existence of peroxyacetyl nitrate (PAN), an irritant and intermediate in ozone smog chemistry, in urban smog. However, it was the advent of commercially available FTIR spectrometers in the 1970s that really allowed the techniques to flourish. FTIR spectrometry provides significant advantages in S/N and spectral resolution over conventional dispersive spectrometry, advantages that can be turned to better detection limits and discrimination between absorbing species. Since the early 1970s, the number and scope of FTIR atmospheric measurements has increased steadily to include

- measurements of ambient air at the earth’s surface, in both clean and polluted air, by either extractive sampling or over open paths in ambient air;
- remote sensing of the whole atmosphere by measurement of the solar absorption spectrum through the atmosphere, or the atmospheric emission spectrum, from the earth’s surface, aircraft and space;
- IR emission measurements for analysis of hot trace gas sources such as stack emissions and volcanic gases.

FTIR atmospheric analysis has a number of advantages over other techniques, including simultaneous analysis of a wide range of trace gas species, in situ, nonintrusive and nondestructive measurements requiring no chemical transformation of the sample, and speed, typically being able to analyze samples in a few seconds to minutes. The principal limitation is the typical detection limits, of the order of a few nanomoles per mole (parts per billion by volume, ppbv) in air.

The objective of this article is to introduce the reader to the principles and applications of FTIR spectrometry in the measurement of atmospheric composition. Within this scope, we focus on the first of the applications above – measurements of ambient air at the earth’s surface. The principles are readily extended to the other methods, and some examples are given in section 6. The article is not intended to be a comprehensive review, nor is it prescriptive in the sense of being a “how-to” manual. It is rather an exposition of the general principles and a selection of applications to illustrate the range of the technique. With this knowledge, extended by relevant references to the literature, it is our intention that the analyst can design and construct his or her own experiment according to the particular requirements of the measurement. Section 2 describes some essential underlying principles of FTIR spectrometry that are required throughout the discussion. Section 3 describes specific details of the FTIR technique as applied to atmospheric measurements. Section 4 provides a brief introduction to the nature of atmospheric IR spectra, and section 5 reviews methods for quantitative analysis of spectra to retrieve atmospheric concentrations. Finally, section 6 describes a selection of applications that illustrate the range of applicability of the technique. Additional information can be found in the books and review articles referred to in each section.

2 Fourier Transform Infrared Spectrometry Essentials

2.1 Basic Principles

FTIR spectrometry has almost completely replaced dispersive spectrometry in the IR region during the 1980s and 1990s. The principles and practice of FTIR spectrometry are well documented in many sources, including articles in this encyclopedia, and it is not the purpose of this article to repeat them. However, a reasonable understanding is crucial in optimizing FTIR operating conditions for atmospheric analysis, and in this section we provide a basic introduction to FTIR spectrometry and in particular the principles governing S/N, spectral resolution and optical throughput.

Figure 1 is a schematic diagram of a typical FTIR spectrometer based on the Michelson interferometer.
Radiation from a source S is focused on to an entrance aperture AP and collimated by a mirror or lens CM. The collimated beam is split into two by the beamsplitter BS. The two beams travel to a fixed mirror FM and a moving mirror MM and return to and recombine at the beamsplitter, half the intensity being directed through the sample to the detector and half returning to the source. (When FM and MM are corner-cube mirrors, the beam returning to the source arm of the interferometer may be laterally displaced and may also be used for sample measurement.) In operation, the moving mirror MM is scanned at a nearly constant speed through the point at which the mirrors FM and MM are equidistant from the beamsplitter and beyond. When the mirrors are equidistant from the beamsplitter, the two beams have an equal optical pathlength or zero optical path difference (OPD), and the recombining beams are perfectly in-phase and interfere constructively in the output beam. As the mirror MM is scanned away from the equidistant point and the OPD increases, the two beams move progressively in and out of phase, and the output intensity measured by the detector for each monochromatic frequency from the source varies sinusoidally with OPD. The variation of output intensity with OPD is called the interferogram, \( I(x) \).

In an ideal spectrometer, if the source were monochromatic, that is, a single frequency of radiation of wavenumber \( \tilde{v} \) and intensity \( B(\tilde{v}) \), the interferogram would be a pure cosine wave (Equation 1):

\[
I(x) = B(\tilde{v}) \cos 2\pi \tilde{v}x
\]  

(1)

If the source is broad band and contains many frequencies, the interferogram is a sum or integral over all frequencies present (Equation 2):

\[
I(x) = \int B(\tilde{v}) \cos 2\pi \tilde{v}x \, d\tilde{v}
\]  

(2)

Equation (2) is one half of a Fourier transform pair, and the spectrum \( B(\tilde{v}) \) can be recovered by computing the Fourier transform of the interferogram (Equation 3):

\[
B(\tilde{v}) = \mathcal{F}\{I(x)\} = \int I(x) \cos 2\pi \tilde{v}x \, dx
\]  

(3)

Equations (2) and (3) provide the simplest description of the operation of an ideal FTIR spectrometer. We provide further details only as they become necessary for our discussion of atmospheric composition measurement.

### 2.2 Spectral Resolution

If the source spectrum is spread over a range of frequencies, ideally they will all interfere constructively at zero path difference (ZPD) and progressively go out of phase as the OPD increases. Thus the interferogram of a broad-band source will be sharply peaked at ZPD and decay as OPD increases. Two frequencies will go out of phase with the OPD quickly if they are widely spaced, and slowly if they are close together. The more closely spaced the two frequencies, the greater must be the maximum OPD to separate them. The apodized spectral resolution \( \Delta \tilde{v} \) of an FTIR spectrometer is usually defined as the inverse of the maximum OPD (Equation 4):

\[
\Delta \tilde{v} = \frac{1}{\text{OPD}_{\text{max}}}
\]  

(4)

### 2.3 Optical Throughput

In Figure 1, the source is focused on to an entrance aperture AP and collimated by the mirror CM. The throughput, \( \Omega \), of the optical system defines the amount of energy transmitted through the optical system. Throughput is analogous to electrical current through a circuit or flow through a pipe – in the absence of losses such as leaks, it is conserved. It is defined by the product of the area of the beam and its solid angle at any focus, for example, the aperture area and the solid angle subtended at the aperture by the collimator, or equivalently the product of the area of the collimated beam and the solid angle of its divergence (Equation 5):

\[
\Omega = \frac{\pi}{4} \phi_A^2 \Theta_A = \frac{\pi}{4} \phi_l^2 \Theta_l
\]  

(5)

where \( \phi_A \) and \( \Theta_A \) are, respectively, the aperture diameter and the solid angle of the beam at the aperture focus (i.e. the solid angle subtended by CM at AP in Figure 1) and \( \phi_l \) and \( \Theta_l \) are the diameter and divergence solid angle of the collimated beam. (For a cone of light with half-angle \( \alpha \), the solid angle \( \Theta = 2\pi(1 - \cos \alpha) \). If \( \alpha \) is small, from the series expansion of \( \cos \alpha \), \( \Theta = \pi \alpha^2 \). A divergent beam is often described by its \( f \) number, the ratio of the focal distance to the diameter of the (assumed circular) collecting mirror or lens. Thus an \( f/4 \) beam has a focal distance-to-diameter ratio of 4. The half-angle of the divergent beam, \( \alpha \), is related to the \( f/\text{no.} \) of the beam by \( f/\text{no.} = 1/2\alpha \). In some low-resolution spectrometers there is no collimator aperture, and the source or detector acts as the effective aperture and limits the throughput.

To obtain a perfectly collimated (i.e. perfectly parallel) beam, the aperture must be infinitesimally small, and the throughput would be zero. The larger the aperture, the greater is the throughput, but the more divergent is the collimated beam. However, the beam divergence in the interferometer, and hence the throughput, are limited by the spectral resolution required because rays traversing the interferometer at different angles to the true optical axis have different path differences
for a given mirror displacement, and their individual contributions to the total interferogram signal “smear out” the OPD at each mirror displacement. Thus the higher the resolution, the less divergence can be tolerated. The optimum throughput is the largest consistent with the spectral resolution at the highest frequency of interest. Quantitatively, the maximum throughput is proportional to the spectral resolution and in practical terms most medium- and high-resolution commercial spectrometers allow a choice of the optimum throughput via the entrance aperture diameter \( \phi_{AP} \) according to Equation (6):

\[
\phi_{AP} = 2FLc \frac{\Delta\tilde{v}}{\tilde{v}_{max}}
\]

where \( FLc \) is the collimator focal length (AP–FM in Figure 1), \( \Delta\tilde{v} \) is the spectral resolution (defined by Equation 4) and \( \tilde{v}_{max} \) is the maximum frequency to be measured. In open-path optical systems for atmospheric analysis, the throughput may be limited by the external optical system rather than the spectrometer resolution and becomes an important design parameter. This is discussed in section 3.2.

### 2.4 Advantages of Fourier Transform Infrared Spectrometry

One of the two major advantages of FTIR spectrometry over dispersive spectrometry is the multiplex or Fellgett advantage, which arises because the detector detects and measures all frequencies in the signal simultaneously, unscrambling them later with the Fourier transform. If the spectrum contains \( N \) resolution elements (e.g. a spectrum from 400 to 4000 cm\(^{-1}\) at 1 cm\(^{-1}\) resolution has 3600 resolution elements), each individual element is measured for \( N \) times longer than in an otherwise equivalent dispersive spectrometer which measures the resolution elements consecutively. Provided that the noise is detector limited, this leads immediately to a resolution improvement (\( \times 60 \) in the above example) in S/N; this is the multiplex advantage. The second major advantage is the throughput or Jacquinot advantage. The throughput of both FTIR and dispersive spectrometers is limited by spectral resolution – in the case of FTIR it is the entrance aperture which is limiting and in the case of dispersive instruments it is the monochromator entrance slit. At a given resolution the FTIR throughput is considerably greater (typically 10–100 times) than that of a typical grating spectrometer.

### 2.5 Signal-to-noise Ratio

The precision and accuracy of a quantitative measurement are determined primarily by the single-beam spectrum S/N in the measured spectrum. Following Griffiths and de Haseth, the S/N is given by Equation (7):

\[
\frac{S}{N} = \frac{S(\tilde{v}) \xi(\tilde{v}) \Delta\tilde{v} \Omega \sqrt{t}}{NEP}
\]

where \( S(\tilde{v}) \) is the source radiance in W cm\(^{-2}\) sr\(^{-1}\) (cm\(^{-1}\) y\(^{-1}\)), \( \xi(\tilde{v}) \) is the efficiency of the optical system (fraction of source energy at \( \tilde{v} \) transmitted), \( \Delta\tilde{v} \) is the spectral resolution (cm\(^{-1}\)), \( \Omega \) is the throughput (cm\(^2\) sr), \( t \) is the measurement time (s) and \( NEP \) is the noise-equivalent-power of the detector (W Hz\(^{-1/2}\)). Of these quantities, \( S \) and \( \xi \) are dependent on the source type and temperature and the spectrometer design and cannot normally be influenced by the experimenter. The detector \( NEP \) may be improved by detector choice, as described below. However for a given hardware configuration, S/N is determined by a trade-off between resolution, throughput and measurement averaging time. If the resolution is doubled (i.e. \( \Delta\tilde{v} \) is halved), S/N is halved and the measurement time required to obtain equivalent S/N increases fourfold. If in addition the optimum throughput is maintained (halved) by reducing the aperture size, the measurement time increases a further fourfold, a total of 16-fold. Clearly, resolution is an expensive commodity on S/N. We shall analyze this trade-off further as we discuss different optical configurations and applications for gas measurements.

### 2.6 Sources and Detectors

Good throughput requires a source with high brightness (i.e. high power emitted per unit area), which for a blackbody emitter depends only on temperature. However, high-temperature filament-type sources such as quartz halogen lamps or xenon arc lamps do not make effective IR sources because the glass or quartz envelope is not transparent in the IR region, and not hot enough to be an effective source itself. Hence the most common IR sources must operate in air, which limits their temperature owing to oxidation. The most commonly used source is the resistively heated SiC globar, typically operating at 1200–1600 K. The size of the source need only be sufficient to fill the field of view of the detector through the optical system (at the largest collimator aperture employed). Once the detector field of view is filled, the only means to improve throughput is to increase the temperature of the source.

Although there are numerous types of IR detector, three types dominate general use in the mid-IR region. Pyroelectric detectors such as deuterated triglycine sulfate (DTGS) are thermal detectors; they are the cheapest and simplest, operating at room temperature, but are also both the slowest and the least sensitive, with response times of the order of milliseconds and detectivities of...

the order of 10⁹ cm Hz¹/² W⁻¹. (Detectivity is defined as $D^* = \sqrt{A_D/NEP}$, where $A_D$ is the detector area, $D^*$ is a measure of the detector's sensitivity on S/N performance independent of its area.) Mercury cadmium telluride (MCT) and indium antimonide (InSb) detectors are quantum detectors and have both faster response times (microseconds) and higher detectivities ($10^{10} – 10^{11}$ cm Hz¹/² W⁻¹) than pyroelectric detectors. Table 1 shows a comparison of typical spectral coverage and detectivity for commonly used, commercially available 1-mm detectors.

The best choice of detector depends on the application. Pyroelectric detectors do not require cryogenic cooling and may be the only choice if liquid nitrogen supply is difficult, as in some in situ and field measurements. For low-resolution studies with high optical throughput, they may be perfectly adequate. In low light level situations (e.g. large multipass cells or long open-path optics as described below), MCT and InSb detectors provide better S/N in spectra (lower NEP, see Equation 7). However, the response of both detectors saturates at high light levels such as in the unattenuated beam of a typical commercial spectrometer, requiring either that overall throughput be reduced (which reduces S/N) or, preferably, that an optical interference filter be used in the optical train to pass only energy in the spectral range of interest. InSb detectors provide the best performance, but only at frequencies above 1800 cm⁻¹.

### 3 EXTRACTIVE AND OPEN-PATH MEASUREMENTS

The preceding section outlined essentials of FTIR spectrometry applicable to any FTIR analysis. This section is concerned with the particular case of measurements in ambient air. There is a fundamental choice of two strategies: to collect the sample and contain it in a closed cell for measurement (extractive sampling), or to collect the spectra over an open path in air. In this section we describe simple and multiple pass (multipass) absorption cells, open-path optical systems and air sampling methods, and summarize the advantages and disadvantages of each.

Concentration detection limits decrease linearly with increasing sample pathlength and S/N in the spectrum. For typical molecular absorptivities, simple short-path cells of 10–20 cm pathlength suffice only to measure relatively concentrated air samples such as combustion gases; pathlengths of tens of meters and more are required to obtain detection limits in the parts per million (by volume; 1 ppmv = 1 µmol mol⁻¹) range and below in ambient air. Long optical paths are obtained by either multiple passing of the beam through the sample in an open or closed cell, or by collimating and projecting the IR beam over a long path in open air. These options are discussed in the following sections. Detection limits are discussed in detail in section 3.4.

### 3.1 Multiple-pass Absorption Cells for Gas Samples

To achieve long pathlengths in an absorption cell of practical size, the beam must be passed through the air sample many times. The most common multipass cell is the White cell, first described by White.

In the White cell (Figure 2), typically located in the focused beam in the spectrometer sample compartment, the convergent FTIR beam is focused into one end of the cell in the plane of the field mirror (FM) and reflects many times between the FM and objective mirrors (OM) before emerging, divergent, on the opposite side of the FM. The beam is refocused on to the FM on each pass so that, after the first pass, the only losses are due to reflective losses on the mirrors. Typically, up to 40 passes of the cell are possible, allowing pathlengths up to 40 m from a cell of 1-m base path. Several variants of the original White cell that double or triple the maximum number of reflections by adding

![Figure 2 Schematic diagram of a White cell, shown set for four passes. The beam enters the cell through one of the windows, focused in the plane of the FM. The OMs collect and refocus the beam on to the FM on every pass. The FM images each OM on to the other. The number of passes is selected by lateral adjustment of one of the OMs such that the beam is refocused at a different spot on the FM at each pass until it exits through the second window after the requisite number of passes.](image-url)
retroreflectors have been described.\(^9\)–\(^{12}\) Multipass cells with pathlengths from <2 m (volume ca. 100 mL) to >100 m (volume 20 L) are commercially available.

For \(N\) reflections and a mirror reflectivity \(\rho\), the transmission due solely to reflective losses is \(\rho^N\). For example, for 40 passes this corresponds to 67% and 45% transmission for reflectivities of 0.99 (e.g. silver) and 0.98 (e.g. gold), respectively. As the pathlength in a White cell is increased, the absorption increases but the radiation intensity and hence S/N decrease; the optimum ratio of absorption to noise is obtained when the transmission due to reflection losses is \(1/e\), that is, \(\rho^N = 1/e = 0.37\).\(^4\)

For reflectivities of 0.99 and 0.98 this corresponds to 100 and 50 reflections, respectively. Thus dirty or degraded mirrors with poor reflectivity lead quickly to a loss of signal and lower S/N in spectra. The other major loss is due to throughput of the cell, which is typically less than the optimum throughput of the spectrometer except at high resolution. For example, for a large 100-m path White cell the beam is typically \(f/15\), and a medium-sized cell with pathlength 10–20 m it is \(f/6\). A typical FTIR beam in the sample compartment is in the range \(f/4–f/6\), so that only for smaller White cells will the entire FTIR beam be captured by the White cell mirrors. After all losses, multipass cells typically have a net transmission of 10–20%.

A different type of multipass cell, based on the Herriott cell,\(^{13}\) is commonly used for tunable IR diode applications. This type of cell provides a much better pathlength to volume ratio than the White cell, but has very low throughput and is not generally suitable for FTIR applications. Recently an integrating sphere has been described for multipassing gas-phase samples in a small volume with a tunable diode laser.\(^{14}\) Based on earlier measurements of cryogenically sampled gases in an integrating sphere,\(^{15}\) this technique should also be applicable to gas-phase FTIR analysis, but to our knowledge has not been described in the open literature.

### 3.2 Open-path Systems

For many applications, such as fugitive emissions monitoring and measurements of reactive gases that are difficult to sample reliably, open path in situ measurements are more appropriate than extractive measurements. To transmit and receive an IR beam along a long path, the beam must be well collimated to minimize inverse-square-law losses due to divergence; according to Equation (5), for a given throughput, the larger the diameter of the collimated beam, the less is its divergence. Two configurations are commonly used and usually referred to as monostatic and bistatic.

In the bistatic configuration, the IR source is collimated by a transmitting telescope and directed to a receiving telescope across the atmospheric path to be analyzed. The receiving telescope collects the beam and focuses it on to an intermediate aperture from which it is then recollimated into the interferometer by the usual collimating mirror. The bistatic configuration is shown schematically in Figure 3(a). It is useful and instructive to examine the theoretical throughput and absorption-to-noise ratio of such a long open-path system. Following Equation (5) and assuming that the solid angle \(\Theta\) can be approximated by \(\pi r^2\), the throughput of the interferometer and telescope systems are given by Equations (8) and (9), respectively:

\[
\Omega_{\text{FTIR}} = \frac{\pi^2 \phi^2_{\text{AP}} \phi^2_{\text{c}}}{16 \ FL^2_{\text{c}}} \tag{8}
\]

\[
\Omega_{\text{tele}} = \frac{\pi^2 \phi^4_{\text{tele}}}{16 \ d^2} \tag{9}
\]

where \(\phi_{\text{AP}}\), \(\phi_{\text{c}}\), and \(\phi_{\text{tele}}\) are the diameters of the intermediate aperture, collimator mirror and telescopes, respectively, (assuming both telescopes have the same diameter), \(FL_{\text{c}}\) is the focal length of the collimator and \(d\) is the distance between telescopes. According to Equation (6), \(\phi_{\text{AP}}\) and hence the throughput of the FTIR system are limited by spectral resolution, while the telescope system throughput decreases as \(1/d^2\) (as required by the inverse square law). As the path \(d\) is increased, up to some critical distance \(d_{\text{max}}\) the throughput of the whole system will be constant and limited by the interferometer, but beyond \(d_{\text{max}}\) it will be limited by the telescope subsystem and decrease as \(1/d^2\). (Equivalently, this can be understood as the image of the transmitting telescope formed by the receiving telescope on the collimator aperture \(\phi_{\text{AP}}\) being larger than \(\phi_{\text{AP}}\) for \(d < d_{\text{max}}\) so that the aperture is overfilled, and smaller than \(\phi_{\text{AP}}\) for \(d > d_{\text{max}}\), underfilling the aperture). The ratio of absorption to noise increases linearly with \(d\) up to \(d_{\text{max}}\), as the pathlength increases but throughput remains constant. For \(d > d_{\text{max}}\), the ratio decreases as \(1/d\) as the throughput decreases as \(1/d^2\) while the absorption increases linearly with \(d\).
Under the assumption that the interferometer collimator and telescopes are \( f \)-matched (i.e., that both have the same \( f \)/number and the beam from the receiving telescope exactly fills the collimating mirror after the aperture), the critical distance \( d_{\text{max}} \) can be calculated from Equations (6), (8) and (9) as Equation (10):

\[
d_{\text{max}} = \frac{\phi_{\text{tele}}^2 F I_{\text{c}}}{\phi_{\text{AP}}} = \frac{\phi_{\text{tele}}^2}{\phi_{\text{c}}} \frac{\sqrt{v_{\text{max}}}}{\Delta v}.
\]

The critical distance thus depends on the resolution, wavenumber and beam diameters and most importantly increases as the square of the telescope diameter \( \Phi_{\text{tele}} \). As an example, Table 2 shows the critical distance \( d_{\text{max}} \) for two typical interferometer configurations: 25-mm diameter beam, 150-mm focal length collimator \( (f/6) \), such as the Bomem MB100 commonly used for open-path measurements, and 50-mm beam diameter, 200-mm collimator \( (f/4) \). The table assumes a 300-mm diameter telescope system \( f \)-matched to the interferometer collimator.

The particular application will determine which system is more suitable.

3.3 Open-path versus Extractive Sampling

Advantages and disadvantages of open-path versus extractive sampling are summarized in Table 3.

3.4 Sampling Methods for Extractive Analysis

For extractive analysis in closed cells, the sample must be collected from the atmosphere and transferred to the cell. Sampling lines should be constructed of inert materials, such as stainless steel or Teflon®. If the line is of significant length or the gas being sampled is at higher than ambient temperature, the intake line may need to be heated to prevent condensation. The simplest method for in situ measurements is to draw the ambient air into the cell for direct measurement if target species concentrations are high enough for detection. The cell may be continually flushed or repeatedly filled and measured in a batch mode. Water vapor can be removed from the sample during collection if desired. The major disadvantage is that regions of the spectrum that are otherwise obscured by the extensive water vapor spectrum become accessible. The major disadvantage is that drying the air may also remove other species, in particular polar compounds. Water vapor...

The canister can be removed from the sample by use of semipermeable membranes (see, for example, United States Environmental Protection Agency (USEPA) Method TO-14A(22)), cryogenic traps or chemical drying agents such as Drierite, magnesium perchlorate or phosphorus pentoxide.

If the spectrometer is remote from the sample site, the air must be collected and returned to the laboratory for analysis. Established methods exist for the collection of air samples in canisters in USEPA Methods TO-14A (nonpolar volatile organic compounds (VOCs))(22) and TO-15 (polar VOCs)(23) While these methods address analysis by gas chromatography (GC) and mass-selective detection, the sampling protocol is also applicable to FTIR analysis. Treated stainless-steel canisters or sorption traps are the most commonly used methods to collect and store the samples. ‘SUMMA’-type canisters have a single valve and a passivated and electropolished or coated inner surface. (SUMMA is a brand name of a particular manufacturer, but it is also commonly used as a generic name for this general type of canister. USEPA Methods TO-14A and TO-15 list a number of suppliers of suitable canisters.) This reduces the potential for loss of sample through adsorption on the canister walls.

Preparation of canisters for sampling involves multiple evacuations and filling with humidified zero air, which is used as the water competes with polar compounds for adsorption sites on the canister and thus reduces losses of trace compounds through this mechanism. The canister should be evacuated for the final time only immediately before sample collection. USEPA Methods TO-14A and TO-15 give procedures for ensuring high-quality canister preparation.

The canister can be passively filled to ambient pressure through natural pressure differential or actively filled (and pressurized above ambient) using a clean, leak-free pump. Under pressurization there is potential for condensation of liquid water, especially with samples taken under conditions of high humidity, which may lead to the loss of water-soluble components from the gas phase. It is also possible to increase the sample pressure with zero air or pure nitrogen at a later stage. This lowers the mixing ratios of the compounds but increases the sample volume, thus allowing multiple measurements.

There have been a number of studies on the long-term storage capabilities of SUMMA-type canisters. Brymer et al.(24) determined that 168 of 194 (86%) of compounds tested could be stored in canisters for up to 30 days without detectable losses. Evans et al.(25) showed that for 31 compounds it was possible to recover 80% or more after 32 weeks of storage. Kelly and Holdren(26) suggested that polar VOCs present more problems, but that canisters are adequate for at least 4 days of storage when the sample is humidified. Both high mixing ratios and high absolute pressure enhanced stability.

Alternative sampling containers include rigid glass canisters. These may have two valves, which allow the canister to be flushed thoroughly with the sample gas before sealing, and the pump may be placed downstream of the container, reducing the risk of contamination. Another method is the use of inflatable bags of inert materials such as Teflon(27), Tedlar(28) or Mylar: the material must be chosen to be both inert to the target gases and not to contribute impurities to the spectra. Sampling bags may be packed into a much smaller volume than rigid canisters, and are always at ambient pressure. They must be inflated with a pump, a potential source of contamination.

An alternative to canister-based collection is the use of adsorption traps. Canister and sorbent-trap sample strategies were compared by Castellnou et al.(27) Evans et al.(25) and Camel and Caudel(28) Such traps are commonly used for collecting samples for GC analysis, and their use is covered extensively in the GC literature (see Camel and Caudel(28) for example). For closed-path FTIR analysis the disadvantage of adsorption traps is that the recovered gas volume is generally low, but may be suitable for particular gases. Sorbent-trap methods may be useful in combination
with a preconcentration strategy. By using adsorbents that are selective, it may be possible to increase the mixing ratio of some components. For instance, by using hydrophobic adsorbents, water vapor may be rejected.\(^{(29)}\)

Consideration must be given to the volume of the sample container relative to the volume of the cell and sampling manifold. SUMMA-type canisters are available in sizes up to at least 15 L, while cell and manifold volumes are typically 10 L or less. If the sample and cell/manifold volumes are approximately equal, then the maximum cell pressure possible would be half of that originally in the sample container, if the sample is transferred by pressure equalization. This may be too low to achieve the desired detection limits. It is necessary then to have a significantly larger sample volume over cell/manifold volume, or incorporate a method to transfer more of the sample from the container to the cell. This may include the use of a mechanical pump or a cryogenic condenser. Hanst and Hans\(^{(30)}\) described a system where the manifold is comprised of relatively large-volume but narrow-bore tubing. After pressure equilibration between the sample container and the cell, the sample container is opened to the atmosphere. This then pushes the sample gas through the manifold and into the cell. Because of the narrow bore there is no mixing between the sample and the ambient atmosphere. The result is that the cell is filled to ambient pressure with sample gas only, while the ambient atmosphere progresses no further than the manifold. It is also possible to transfer nearly the complete volume through the intermediate step of cryogenic condensation of the sample from the sample container, then vaporization into the cell.

### 3.5 Detection Limits

Absorption in IR spectroscopy is ideally described by Beer’s law. Radiation intensity decreases exponentially with the concentration and pathlength through an absorber (Equation 11):

\[
I(\tilde{\nu}) = I_0(\tilde{\nu})e^{-\alpha(\tilde{\nu})cI}
\]

or equivalently the absorbance \(A(\tilde{\nu})\) increases linearly with concentration and pathlength (Equation 12):

\[
A(\tilde{\nu}) = \log_{10}\left(\frac{I_0(\tilde{\nu})}{I(\tilde{\nu})}\right) = \alpha(\tilde{\nu})cI
\]

where \(I_0(\tilde{\nu})\) and \(I(\tilde{\nu})\) are respectively the radiation intensity at frequency \(\tilde{\nu}\) before and after traversing the sample, \(\alpha(\tilde{\nu})\) is the absorptivity of the absorber (also called the absorption coefficient), \(c\) is the absorber concentration and \(I\) the optical pathlength through the sample. (All logarithms are assumed here to be decadic. Thus \(\alpha(\tilde{\nu})\) in Equation 11 is 2.303 times \(\alpha(\tilde{\nu})\) in Equation 12.)

Quantitative analysis should be performed on absorbance spectra because in the Beer’s law approximation absorbance is linear in absorber amount. The minimum detectable amount (i.e. concentration–pathlength product) of an analyte is given by Equation (13):

\[
[c]_{\min} = \frac{A_{\min}(\tilde{\nu})}{\alpha(\tilde{\nu})}
\]

where \(A_{\min}(\tilde{\nu})\) is the minimum detectable absorbance, assumed here to be equal to the peak-to-peak (p–p) noise level in the spectrum (For normally distributed noise, the p–p noise level is typically 4–5 times the root mean square (RMS) noise level; the single-beam S/N is equal to 1/(2.303 \times noise in absorbance)). At this level of absorption the feature would normally be identifiable by eye, and when using full spectrum fitting techniques such as classical least squares (CLS) or partial least squares (PLS) (see section 5) for quantitative analysis a quantitative determination should be possible. Other authors variously use two or three times the spectral noise level; the actual choice should be clearly stated. The p–p noise level in absorbance spectra will typically be in the range 0.01 (long open path, DTGS detector, poor throughput) to 0.0001 (good throughput, closed cell, MCT or InSb detector).

For the best concentration detection limit, the pathlength, absorptivity and S/N should therefore be as large as possible. The pathlength will be determined by the experiment as discussed earlier. The true absorptivity is a molecular property and clearly the strongest absorption bands of the analyte should be used if possible. However, for sharp absorption lines the apparent absorptivity will decrease at low spectral resolution, as discussed below. The most important determining factor for detection limits then becomes the spectral S/N. Interference from other absorbing species, in particular water vapor and carbon dioxide (section 4), may reduce detection limits below the S/N-limited values.

We can distinguish two limiting cases, depending on whether the spectral bands are much wider or much narrower than the instrument spectral resolution.

(a) Spectral bands broader than instrument resolution. This is the simpler case and applicable for larger molecules where the fine structure of the absorption bands (due to molecular rotation) is not spectrally resolved. Such bands may be 10–20 cm\(^{-1}\) wide and will be well resolved with 4–8 cm\(^{-1}\) resolution or better. In this case the observed peak heights will be independent of resolution and determined only by the absorptivity and absorber amount. The lowest resolution that still resolves the broad bands should be selected since this will maximize S/N (Equation 7). Absorptivities are normally quoted in units of atm\(^{-1}\) cm\(^{-1}\) or cm\(^{2}\) molecule\(^{-1}\). For 1-atm pressure at 296 K, 1 atm cm
is equivalent to $2.5 \times 10^{19}$ molecules cm$^{-2}$ or $10^4$ ppmv m. Typical peak absorptivities for medium to large molecules are in the range $1$–$100$ atm$^{-1}$ cm$^{-1}$, corresponding to $10^{-4}$–$10^{-2}$ ppmv m$^{-1}$. For these extreme values of $\alpha$ and typical noise levels of $0.01$–$0.0001$ in absorbance, Table 4 shows the corresponding detection limits in ppmv m; for example, a detection limit of 1 ppmv m corresponds to 1 ppmv over a 1-m path, 0.01 ppmv over a 100-m path, and so on. Over a 100-m path, detection limits typically lie in the range 1 ppmv–50 pptv.

(b) Spectral bands narrower than instrument resolution. This will be the case for many smaller molecules with resolved rotational structure, for which pressure-broadened linewidths at 1 atm pressure are typically $0.05$–$0.15$ cm$^{-1}$. Unless high resolution ($\Delta \tilde{v} < 0.1$ cm$^{-1}$) is used, the measured peak absorptivities will be approximately inversely proportional to the resolution $\Delta \tilde{v}$. Peak heights will increase with resolution (inversely with $\Delta \tilde{v}$), but S/N will decrease in proportion to either $\Delta \tilde{v}$ or $\Delta \tilde{v}^2$, depending on whether or not throughput is reduced by reducing the spectrometer aperture (section 2.5). In the former case there is no penalty.

$^a$ Minimum detection limit in ppbv, 100-m path, $10^{-4}$ absorbance noise (base 10).

fwhm, full width at half-maximum.
in detection limits for higher resolution since the peak heights and noise level increase together, and the higher resolution may help in identifying and separating spectral lines. In the latter case, however, higher resolution will lead to lower S/N and consequently lower detection limits. The lowest resolution acceptable for analysis of the resulting spectra with acceptable discrimination between absorbers should then be chosen.

Strong individual lines of small molecules, for example, CO$_2$ in the v$_3$ band near 2350 cm$^{-1}$, may have true peak absorptivities up to 500 atm$^{-1}$ cm$^{-1}$ at 1 atm pressure and high resolution. The apparent absorptivities will be reduced if the resolution is lower than the intrinsic width of the pressure-broadened lines, 0.05–0.15 cm$^{-1}$. Since both individual coefficients and linewidths vary widely, it is more difficult to generalize on detection limits in these cases.

Collections of quantitative reference spectra are available both commercially and in the public domain; details are given in the Appendix. Once absorptivities and experimental parameters such as resolution and noise level are known, the principles of this section may be used to estimate detection limits. Interference from atmospheric water vapor and carbon dioxide absorption may affect the estimate detection limits in polluted atmospheres or plumes, together with apparent peak absorptivities at 0.5 cm$^{-1}$ resolution and corresponding detection limits assuming a 100-m path of clean air at 1 atm, 25°C. Typical mid-IR absorption spectrum of 100-m path of clean air with the principal absorption bands shown. Figure 4 shows a typical atmospheric absorption in clean air over pathlengths up to a few hundred meters is dominated by absorption of minor and trace gases, principally water vapor (0–4% by volume depending on humidity) and carbon dioxide (360 ppmv). Figure 4 shows a typical atmospheric transmission spectrum over a 100-m path in clean air with the principal absorption bands shown. The most useful windows for detection of additional absorbers are between the water vapor and carbon dioxide absorption features.

3.6 Choice of Spectral Resolution

From the above, it is clear that the selection of spectral resolution for a measurement is a critical choice. While the spectroscopist would argue for high resolution to resolve all bands, the analytical chemist would argue for the lowest acceptable resolution to maximize S/N and quantitative precision. In practice, a balance must be struck to suit the demands of the individual measurement, and this requires an informed judgement by the operator. To some extent resolution will, of course, be limited by available hardware. Low-resolution spectrometers have the advantage of being cheaper, smaller and in principle more robust since the scanning mechanism need not maintain alignment over long scan lengths. Throughput is higher, leading to better detection limits. The main limitation will be for conditions where higher resolution is required to discriminate spectral features that cannot be separated by the quantitative analysis methods employed. For example, peak height- or peak area-based methods require that the band being analyzed be reasonably well resolved from interfering absorptions with a well-defined baseline, whereas full spectrum methods such as CLS and PLS (section 5) can often discriminate between absorbers even when their bands overlap.

Several authors have discussed the choice of resolution in long open-path monitoring when using CLS analysis (section 5.4). While there is no definite ‘best’ resolution, there is a general consensus towards 1–2 cm$^{-1}$ as a reasonable compromise between spectral discrimination of overlapping bands and quantitative accuracy. Griffiths and co-workers make the case that lower resolution (8 cm$^{-1}$) may be practical when using PLS (section 5.5) for quantitative analysis.

4 ATMOSPHERIC INFRARED SPECTRA

All molecules except homonuclear diatomics exhibit IR spectra due to the vibrations and rotations of the molecules. Thus we are fortunate that the major fixed components of air, N$_2$ (78% of dry air), O$_2$ (21%) and Ar (1%), are transparent to IR radiation, and atmospheric absorption in clean air over pathlengths up to a few hundred meters is dominated by absorption of minor and trace gases, principally water vapor (0–4% by volume depending on humidity) and carbon dioxide (360 ppmv). Figure 4 shows a typical atmospheric absorption in clean air over pathlengths up to a few hundred meters is dominated by absorption of minor and trace gases, principally water vapor (0–4% by volume depending on humidity) and carbon dioxide (360 ppmv).
dioxide absorptions in the approximate ranges 800–1200, 2000–2300 and 2400–3000 cm\(^{-1}\), of which the first corresponds largely to the so-called “fingerprint region” in which most molecules have characteristic absorption bands.

Each absorption band in the IR spectrum corresponds to a particular molecular vibration, with shape or fine structure determined by concomitant rotational transitions. Individual vibration–rotation transitions are broadened by two mechanisms:

- **Pressure broadening**, due to the perturbation of molecular energy levels by collisions between molecules. This broadening varies from molecule to molecule and line by line and is proportional to pressure, has a Lorentzian lineshape, and typical linewidths (fwhm) of 0.05–0.15 cm\(^{-1}\) atm\(^{-1}\).

- **Doppler broadening**, due to the random distribution of molecular velocities around the mean velocity. Doppler broadening increases with the square root of temperature and decreases as the square root of molecular mass. For small to medium-sized molecules at ambient temperatures, Doppler linewidths (fwhm) are typically 0.002–0.004 cm\(^{-1}\).

The general, combined lineshape is called the Voigt lineshape. Under normal ambient atmospheric conditions, collision or pressure broadening dominates and individual absorption lines generally have a near-Lorentzian lineshape and linewidths of the order of 0.1 cm\(^{-1}\). In smaller molecules the individual vibration–rotation transitions are usually well separated compared with their linewidths. In larger molecules the rotational lines become more closely spaced, as to a first approximation the spacing scales inversely with the mass and the square of the molecular size. Typically, in molecules with molecular masses much over 100, the rotational lines are more closely spaced than their linewidths and merge together into a broad band profile for each vibrational transition. Figure 5(a–c) illustrates typical vibration–rotation band spectra of molecules which show the gradation from resolved rotational structure in carbon monoxide (CO) through partially merged rotational lines in nitrous oxide (N\(_2\)O) to a smooth profile in toluene (C\(_6\)H\(_5\)CH\(_3\)).

The actual appearance of measured spectra depends in addition on the spectral resolution. If the resolution is three or more times higher (i.e. $\Delta \tilde{v}$ lower) than the intrinsic linewidths, the true spectra will be faithfully reproduced, but this may come at a significant cost in S/N (section 2.5) and complexity in the experimental configuration. At lower resolution ($\Delta \tilde{v}$ greater than the intrinsic linewidths), the detailed band structure may be wholly or partially lost so that only a broad band profile is observed. This may lead to a loss of selectivity between compounds but with a gain in S/N at the lower resolution. The ideal resolution for a particular analysis requires a considered judgement by the experimenter.

## 5 CALIBRATION AND QUANTITATIVE ANALYSIS

Several methods present themselves for calibration and quantitative analysis of measured spectra, and the choice of the best method is an integral part of the analysis strategy. Most methods are based on Beer’s law (Equation 12), in which the absorbance is proportional to the amount of absorber present in the beam. Deviations from Beer’s law are fairly common, however, especially at low resolution, and are discussed.
in section 5.7. In increasing order of complexity, we briefly review here peak height/area measurements, spectral subtraction, CLS, factor analysis methods such as PLS and principal components regression (PCR) and nonlinear least squares. Haaland\textsuperscript{[39]} provides a detailed overview of calibration methods with references to further details of each individual method.

5.1 Measurement of Background Spectra

In all but nonlinear least squares, Beer’s law requires that absorbance spectra be used, which in turn requires that a background \((b_0)\) spectrum be recorded in addition to the sample spectrum. Closed-cell measurements present no great difficulty in recording a background spectrum of either the evacuated cell or the sample cell flushed with clean background air or a nonabsorber such as \(N_2\). Open-path measurements are more difficult since the sampled volume cannot be so easily manipulated. Possible methods for background spectrum measurement include the following:\textsuperscript{[18,38]}

1. Synthetic background spectrum. By selecting points in a sample spectrum estimated to have negligible absorption, a smooth curve through these points can be constructed. Most spectrometer software will allow this procedure but it requires user skill and judgement and has many potential pitfalls. It should be used only when the collection of real background spectra is impractical, and preferably only over narrow frequency intervals.

2. Upwind background spectra. Collect spectra upwind of the path to be investigated so that none of the target gases appear in the background spectrum. This requires an experimental set-up in which the optical path can easily be redirected, e.g. by having two retroreflectors in a monostatic open-path configuration.

3. Short-path spectra. Record background spectra over a very short path relative to the path for sample measurements by bringing the source or retroreflector close to the spectrometer. Care must be taken not to saturate detectors with this method since there will be much greater throughput for the short path.

None of these methods is ideal in that none provides a background spectrum identical to the sample spectrum except for the lack of sample. The best choice will depend on the experimental configuration, measurement site and conditions and available hardware.

5.2 Peak Height or Area Analysis

The simplest and most traditional quantitative analysis method is to measure either peak height at a particular frequency or integrated peak area over a restricted frequency range in an absorbance spectrum. The amount of absorber \(c_l\) is calculated directly from the measured absorbance (or integrated absorbance) and the known absorptivity assuming Beer’s law, \(c_l = A_l/\alpha\). The peak or integrated absorptivity is determined by an equivalent analysis of a set of calibration spectra of known amounts; the slope of a Beer’s law plot of absorbance versus amount yields the absorptivity. If the Beer’s law plot is nonlinear it may still be used as a calibration curve. Peak area is in principle better than peak height because the absorbance integrated over a peak is to a good approximation independent of the resolution and intrinsic lineshape provided the absorbance is not too large. These peak-based methods, although quick and relatively simple, have potential drawbacks and should be used with caution or only for initial estimates of concentrations. Both methods require that the peak be reasonably isolated from other spectral features so that a baseline from which the height or area is measured can be estimated; this requirement is particularly stringent for peak areas. Software provided with commercial FTIR instruments normally has the ability to perform quantitative analysis based on peak area and height.

5.3 Interactive Subtraction

If Beer’s law is obeyed, the absorbance spectrum of a mixture of gases is simply the sum of the spectra of the individual gases weighted according to their respective amounts. At any wavenumber the absorbance is given by Equation (14):

\[
A_{\tilde{v}} = \alpha_{1,\tilde{v}}(cl)_1 + \alpha_{2,\tilde{v}}(cl)_2 + \alpha_{3,\tilde{v}}(cl)_3 + \cdots \tag{14}
\]

where the subscripts 1, 2, 3, ... refer to the individual compounds contributing to the spectrum at frequency \(\tilde{v}\). If reference absorbance spectra of the individual compounds are available, they can be sequentially subtracted from the total spectrum until in principle only noise remains in the residual spectrum. Most spectrometer software provides the facility for interactive subtraction of a scaled reference spectrum from a measured spectrum. The scaling factor is interactively adjusted until the residual spectrum appears by eye not to contain any contribution from the reference spectrum. The scaling factor then provides the amount of reference compound in the measured spectrum. Clearly a region of the spectrum should be chosen for this process where the absorption features of the reference compound dominate all others in the spectrum. This method is intuitive and instructive for gaining a good “feel” for the nature of measured spectra. It also uses more of the measured spectral data over a wider range of frequencies than peak-based methods, which adds to the information content of the method.
However, it requires a degree of practice and skill for consistent quantitative results, which are somewhat subjective since the ultimate criterion used to decide the scaling factor is a judgement by eye. Care should be taken to match the resolution, apodization, lineshape and spectral shifts of sample and reference spectra or a good fit will never be achieved.

CLS methods are based on the same premise (Equation 14) but use a more rigorous criterion for goodness of fit and are described next.

5.4 Classical Least Squares

CLS is the simplest of the multivariate least squares techniques and perhaps the most commonly used method for quantitative analysis of atmospheric spectra. CLS is also based on Beer’s law in the form of Equation (14), which can be written at each frequency over a suitable spectral range for analysis of the target gases to provide a set of equations linear in the unknown amounts. Provided there are more frequencies in the selected spectral region than unknown components (i.e. more equations than unknowns), the set of equations is overdetermined and the amounts can be determined by standard methods of least squares regression. In essence, a linear combination of single-component reference spectra of the individual compounds is fitted to the measured spectrum such that the sum of the squares of the residuals at each frequency is minimized. The amounts of each absorber required in the best fit provide the required quantitative result. The method is similar to spectral subtraction except that the rigorous least squares criterion is used to determine the best fit. The equations for the regression can be readily written and solved in matrix form so that the method is computationally fast and efficient. The matrix of absorptivities is often called the K-matrix and CLS regression equivalently called the K-matrix method.

Calibration in CLS is the determination of the basis set of single component spectra to be used in fitting the unknown spectra. Ideally the reference spectra should be measured with the same spectrometer under the same conditions as the unknown measurement so that the environmental (e.g. temperature, pressure) and instrumental (e.g. instrument lineshape, background, wavenumber shifts) effects on spectra are the same in the reference as in the sample spectra. The spectra can be measured directly as single pure component spectra or as mixtures, in which case a CLS calibration step is used to determine (again by least squares regression) the best single-component spectra which fit the “training set” of calibration spectra. Such calibration may be very laborious and time-consuming, especially if many compounds are involved; in practice, such calibration is seldom undertaken in the field. Reference spectra are more commonly generated in the laboratory and stored, or taken from publicly or commercially available libraries (see Appendix). For open-path measurements, the reference calibration spectra cannot be recorded in an equivalent experimental configuration, and cell or library spectra must be used. As for all subtraction methods, great care must be taken to match the resolution, apodization, lineshape and spectral shifts of sample and reference spectra or poor fits with large residuals will result. An alternative approach to generation of reference spectra is to calculate the spectra, as described in section 5.6.

CLS has the advantage that it is conceptually and computationally simple, and is often well suited to gas-phase analysis. It is in principle more accurate than peak height or area measurements because it uses the information contained in an extended range of frequencies in the quantitative analysis, rather than just a few over a single peak. However, there are two major drawbacks. First, CLS requires that all compounds absorbing in the analyzed spectral region be included in the CLS reference set. If not, the residual spectrum will still contain the spectrum of the missing components and the method may determine incorrect amounts of other gases in a false attempt to minimize the total spectral residual. This sort of error is readily identified by observing the full spectrum residual after the CLS fit – if all absorbers have been accounted for, and the residual should consist of only noise. If reference and sample spectra have different instrumental lineshapes and shifts, these will also be apparent in the residuals. The second major drawback is that CLS relies implicitly on Beer’s law, since the fitted spectrum is constructed as a simple linear combination of reference absorbance spectra. Breakdown of Beer’s law is discussed in section 5.7; for gas-phase spectra the problems are most severe for medium-to-strong absorption in low-resolution spectra of molecules with resolved rotational structure. In this case care must be taken to minimize the impact of Beer’s law nonlinearity.

The USEPA currently recommends CLS as the preferred method for analysis of open-path spectra, as set out in detail in the Compendium Method TO-16, “Long-path open-path FTIR monitoring of atmospheric gases”. This document sets out explicit methods and recommendations for most aspects of CLS analysis including window determination, avoidance of interferences and minimization of the effects of Beer’s law breakdown. Software for general-purpose CLS is available in many commercial spectrometer packages.

5.5 Partial Least Squares

PLS and its relation PCR are, like CLS, full spectrum methods which construct a fit to a measured
spectrum from a linear combination of basis spectra. In PLS and PCR, however, the basis spectra are not pure single-component spectra. The first step of a PLS or PCR calibration is to create a training set of mixture spectra which should span the range of natural variation to be expected in the samples to be analyzed. A factor analysis is performed on the training set to find a set of factors or “pseudo spectra” which form the basis set and are sufficient to explain all significant variance in the training set, that is, each training spectrum (and, during prediction, each sample spectrum) can be reconstructed as a linear combination of the factor spectra weighted by a score for each factor. PLS and PCR differ only in the method by which the factor analysis is performed. In the first instance, it is not necessary to know the complete composition of the training spectra. For those components for which concentrations in the training spectra are known, the concentrations are regressed against the factor scores to link the factor analysis to the known concentrations in the calibration spectra. For analysis of an unknown sample, first the unknown spectrum is fitted as a linear combination of the factors, much the same as CLS where the fitting spectra are the pure single-component spectra. Second, the amount of each component known to the calibration is calculated from the fitted factors and the scores in a second linear regression.

PLS also assumes Beer’s law to hold, but to some extent nonlinearities due to Beer’s law breakdown will be modeled during the factor analysis and accounted for as extra factors in the basis set. These non-Beer’s law components include baseline variations, nonlinearities and the existence of complexes or even reaction products between the individual compounds. For analysis of multicomponent mixtures, PLS thus has some significant advantages over CLS in the general case, but if the limitations of CLS are recognized and can be taken into account as described above and in section 5.7, CLS is simpler and provides equivalent results which are easier to interpret.

Johansen et al.⁴² provided a good example of PLS use for open-path monitoring of air quality in a spacecraft capsule, building a calibration model for 23 separate gases, including corrections for baseline drift and mirror degradation. The calibration training spectra are built from single-component spectra, digitally combined into mixture spectra and baseline variations are built into the model. High absorbance regions are avoided to minimize Beer’s law limitations (section 5.7). More recently, Griffiths and co-workers⁴³ proposed PLS methods for general open-path monitoring. A large database of real atmospheric spectra collected over a range of pathlengths, temperatures, pressures, spectrometer variations and background concentrations of water vapor and carbon dioxide is used as a set of background spectra to which known amounts of reference spectra of target compounds from the USEPA library (see Appendix) are added digitally to create the calibration training set. Good results have been demonstrated using wide spectral windows at relatively low resolution (8 cm⁻¹), which allows the use of smaller, cheaper and more compact FTIR spectrometers employing only pyroelectric detectors. Genetic algorithms have been used in optimizing window selection⁴⁴ and neural network techniques in compound identification.⁴³ These PLS methods provide an alternative approach to CLS methods as embodied for example in the USEPA TO-16 document.⁴¹

5.6 Calculation of Synthetic Calibration Spectra

An alternative method of acquiring calibration spectra is to calculate them. Griffith⁴⁵ described a method in which synthetic calibration spectra are calculated from a database of absorption line parameters such as HITRAN.⁴⁶,⁴⁷ The program MALT (Multiple Atmospheric Layer Transmission) first takes the standard absorption line parameters, corrects and scales them to the concentrations, pathlengths, temperature and pressure assumed for the calculated spectrum, and convolves them with the pressure and Doppler lineshape contributions to provide the true monochromatic atmospheric transmission spectrum. The monochromatic spectrum is then convolved with an instrument lineshape function including the effects of finite resolution, field of view divergence, apodization and spectral shift. In later improvements (to be published), effects of phase error, spectrometer misalignment and other spectrometer imperfections can be included. The calculated spectra then closely model true measured spectra on a real spectrometer. The program can be used to calculate whole sets of calibration spectra for any environmental and instrument operating conditions quickly and accurately, and the calibration spectra used, for example, as a training set for CLS or PLS analysis.

The synthetic spectrum approach is fast, reproducible and convenient and when combined with CLS analysis as described below (section 6.3) provides precision (reproducibility) of much better than 1% and absolute accuracy of 1–5% without any need for calibration gases. It is a particularly useful option for open-path spectra where true calibration or reference spectra cannot easily be measured, but is also a practical basis for cell-based gas analysis. Calculating reference spectra is the only practical option for nonlinear least squares (NLLS) analysis and in particular the analysis of solar absorption spectra (section 6.7). The major drawback is the range of species for which the method is applicable—line parameters must be available. The HITRAN database is publicly available and covers 37 molecules.
listed in the Appendix.\textsuperscript{(47)} Other databases have also been developed.\textsuperscript{(48,49)} It is also possible to combine calculated and library spectra in a single CLS or PLS calibration training set.

5.7 Limitations to Beer’s Law

Beer’s law holds strictly only at infinite resolution, that is, when the spectrometer does not distort the true spectral lineshapes. The most common way in which Beer’s law breaks down is when the true linewidths of absorption features are comparable to or narrower than the spectral resolution. In this case the absorbance is linear with absorber amount at low absorbance but increasingly falls off at higher absorbance. Anderson and Griffiths\textsuperscript{(50)} and Zhu and Griffiths\textsuperscript{(51,52)} give a detailed account of this behavior. This can be a serious problem for small molecules with resolved rotational structure in their spectra. Typical linewidths of individual lines at 1-atm pressure are 0.05–0.15 cm\textsuperscript{-1}, which would require spectra at high resolution to avoid such Beer’s law nonlinearities. Since many atmospheric measurements are made with compact spectrometers with resolution typically 0.5–4 cm\textsuperscript{-1}, this form of Beer’s law breakdown can often not be neglected. Haaland\textsuperscript{(53)} discusses several means to minimize the effect of Beer’s law nonlinearity on CLS analysis; these are illustrated in Figure 6 and may be summarized as listed below.

1. Calibrate only over a narrow concentration range about the concentration range of interest to avoid excessive curvature in the Beer’s law (absorbance vs absorber amount) calibration curve.

2. Allow for an intercept in Beer’s law, i.e. assume that \( A = a_0 + a_1 c_l \) in the calibration model (line (c) in Figure 6). This allows a curved section of the Beer’s law calibration curve to be better approximated by a straight line since the straight line is not constrained to pass through the origin.

3. Allow for quadratic terms in the Beer’s law model, i.e. \( A = a_0 + a_1 c_l + a_2 (c_l)^2 \). This model allows an approximation to the curvature in the true \( A \) vs \( c_l \) curve but is still linear in the coefficients \( a \) and the formalism of CLS can still be applied.

Beer’s law also breaks down if components in the sample interact and perturb the individual pure-component spectra and/or add spectra of some inter-action complex, so that the spectrum of the mixture is not a linear sum of the pure-component spectra. This is not a serious problem in gas-phase spectra of the ambient atmosphere, but may be in concentrated samples such as stack effluent or combustion products. PLS would be better used in these cases.

5.8 Nonlinear Least Squares Analysis

NLLS analysis provides a different approach to quantitative analysis which does not rely on the implied linearity of Beer’s law. NLLS constructs a fit to a measured spectrum by calculating spectra iteratively until the spectral residual between calculated and measured spectrum converges to an acceptable minimum.\textsuperscript{(54,55)} An initial guess is made about the parameters describing the unknown spectrum and the spectrum is calculated with a program such as MALT described above. The two spectra are compared, the calculation parameters refined, the spectra recalculated and recompared, and the process repeated until satisfactory agreement between measured and calculated spectra is obtained. The search method for the best fit is usually based on the commonly used Levenberg–Marquardt algorithm.\textsuperscript{(56)}

This method is used almost exclusively in the analysis of solar absorption spectra through the atmosphere, since the inhomogeneity and variability of the atmosphere with altitude and time make the use of any sort of measured reference spectra impossible for quantitative analysis. Some examples are described in section 6.7. NLLS could be readily adapted to long open-path or closed-cell measurements, and would have particular advantages in cases where Beer’s law is not obeyed since it makes no assumptions about linearity between concentrations and measured absorbance. One drawback with this method is that it is computationally intensive since the spectrum must be recalculated on each iteration of the fit. However, with the power of modern desktop computers, calculation times have

![Figure 6](image-url) Illustration of deviations from Beer’s law. (a) Ideal; (b) typical deviation at low-resolution; (c) linear approximation to (b) with intercept \( \alpha \). The dotted lines illustrate the desired calibration range.
been reduced to a few seconds per spectrum and this is no longer a serious limitation. To our knowledge there is currently no ready-written software commercially available for NLLS analysis of gas phase spectra.

6 SELECTED APPLICATIONS

In this section we describe a selection of applications of atmospheric analysis by FTIR spectrometry. The coverage here is not intended to be a thorough review, rather it is a selection which illustrates various applications of the technique. More detailed reviews are quoted in the text, and the biannual reviews of IR spectrometry in Analytical Chemistry provide a regular, thorough review of work published. The two most recent reviews are by Mckelvy and co-workers.\textsuperscript{[57,58]}

6.1 Early History – Measurements of Urban Pollution Chemistry by Fourier Transform Infrared Spectrometry Using Long-path Cells

Long-path IR studies of atmospheric chemistry were pioneered by Stephens and co-workers in the 1950s.\textsuperscript{[3,4,59,60]} Using long-path cells of up to 400-m pathlength and dispersive spectrometers, these studies achieved sensitivities in the ppmv range, and laid much of the important groundwork for the technique. This work concentrated on the chemistry of urban photochemical pollution and formation of photo-oxidants such as ozone, and provided the first identification of PAN,\textsuperscript{[3]} one of the most important secondary pollutants in urban smog.

The sensitivity of these measurements was limited, however, by the use of dispersive spectrometry, and was insufficient for routine measurements except in the most polluted ambient air. The advent of FTIR spectrometers in the 1970s increased the utility and potential of the method enormously. Throughout the 1970s and 1980s, Hanst, Pitts and co-workers, working at the USEPA and the Statewide Air Pollution Research Center in Riverside, California, developed the technique further with commercial FTIR spectrometers and multipass cells with pathlengths of >1 km.\textsuperscript{[11,61–66]} This work also focused on urban pollution and photochemical smog in the Los Angeles basin, and with FTIR spectrometry was able to detect and quantify pollutant species at ppbv levels in ambient air. One of the major attractions of the technique was the ability to measure a wide range of volatile organic, nitrogen- and sulfur-containing compounds simultaneously and nonintrusively. The large cells could be used for both ambient air monitoring and as smog chambers for photochemical kinetic studies. They played a major role in elucidating the chemistry of urban smog.

Hanst and Hans\textsuperscript{[30]}

6.2 Open-path Monitoring of Air Pollution and Fugitive Gases

The USEPA also fostered the early development of open-path monitoring by long-path FTIR spectrometry with the ROSE (Remote Optical Sensing of Emissions) system.\textsuperscript{[67–69]} which was trialed in a variety of applications, including emissions from phosphate fertilizer waste treatment ponds (HF, SiF\textsubscript{4}), engine exhausts (CO, hydrocarbons, CH\textsubscript{2}O), oil refinery emissions (hydrocarbons, methanol, SO\textsubscript{2}) and power plant and waste incinerator stack emissions (CO, CO\textsubscript{2}, hydrocarbons, NO, NH\textsubscript{3}, HCl). However, the real growth in open-path FTIR monitoring techniques and applications took place in the 1990s, driven largely by tighter government clean air regulations such as the US Clean Air Act Amendments of 1990.\textsuperscript{[70]} The applicability of open long-path FTIR spectrometry to monitor many species simultaneously and nonintrusively at ppbv levels in many cases fits well with increased requirements on industry to monitor and control fugitive emissions from chemical plants and refineries, and monitoring the clean-up of chemically contaminated sites.

For example, Fateley and co-workers\textsuperscript{[19,71,72]} describe fenceline monitoring at chemical plants, contaminated site remediation studies and remote measurements of gaseous emissions from volcanoes using open-path systems based on Bomem and Midac spectrometers at medium (typically 0.5 cm\textsuperscript{–1}) resolution. Haus and co-workers\textsuperscript{[73,74]} describe a higher resolution (0.25 cm\textsuperscript{–1}) spectrometer for both long-path absorption and IR emission studies in clean air, pollution studies and smoke stack and flare emissions. Galle and co-workers\textsuperscript{[75]} used 200-m and 1-km open-path white cells combined with a 1 cm\textsuperscript{–1} Bomem spectrometer described in section 3.2 as an open-path monitor in a number of industrial fugitive gas and greenhouse gas monitoring situations. They described the use of tracer gases such as SF\textsubscript{6} and N\textsubscript{2}O deliberately released with the target gases to obtain quantitative estimates of fluxes from various sources.\textsuperscript{[75]}

Although earlier work was mostly done at relatively high resolution to resolve the individual spectral lines, long open-path FTIR monitors have been increasingly based on lower resolution (0.5–4 cm\textsuperscript{–1}), more compact, mobile and affordable spectrometers and combined withCLS and PLS quantitative analysis to resolve overlapping absorptions. Recent reviews, and published proceedings of a regular series of conferences by the
Air and Waste Management Association and the SPIE (International Society for Optical Engineering) on optical remote sensing for environmental monitoring, provide a more detailed overview and many further examples of applications.\textsuperscript{[76–83]} The USEPA has published two detailed reports on open-path FTIR monitoring, the first a guidance document for use of the technique,\textsuperscript{[88]} and the second the more formal and prescriptive Compendium Method TO-16 “Long-path open-path FTIR monitoring of atmospheric gases”\textsuperscript{[81]}

6.3 High-precision Measurements of CO\textsubscript{2}, CO, CH\textsubscript{4}, N\textsubscript{2}O and \textsuperscript{13}CO\textsubscript{2}/\textsuperscript{12}CO\textsubscript{2} in Clean Air

CO\textsubscript{2} and CH\textsubscript{4} are the two most important greenhouse gases, N\textsubscript{2}O is both a minor greenhouse gas and the principal source of stratospheric nitrogen oxides for ozone depletion and CO plays a crucial role in the background photochemistry of the atmosphere.\textsuperscript{[84]} High-precision measurements of these gases are regularly made by GC and nondispersive infrared (NDIR) techniques in clean air at a network of global monitoring stations in order to understand their global source and sink budgets and impacts on global change. These four gases are also the most abundant IR-absorbing atmospheric trace gases in clean air (excluding H\textsubscript{2}O), with typical mixing ratios of around 360 ppmv, 1700 ppbv, 310 ppbv and 50–100 ppbv, respectively. We have developed long-path FTIR spectrometry to monitor these gases simultaneously, cost effectively and with high precision.\textsuperscript{[85,86]}

Spectra of dried air in 10- or 22-m White cells are recorded with a Bomem MB100 spectrometer at 1 cm\textsuperscript{-1} resolution using an InSb detector for low noise levels. The spectrometer and cell are carefully temperature controlled to maintain good stability. We use MALT-calculated calibration spectra and CLS quantitative analysis as described in section 5.6 \textsuperscript{[45]} and achieve relative precision (i.e. repeatability) of better than 0.1% for CO\textsubscript{2}, CH\textsubscript{4} and N\textsubscript{2}O and 0.5% for CO. Absolute accuracy is of the order of 1–5% without any need for measurement of calibration gases, that is, with calibration based only on the MALT–HITRAN calculation. Higher absolute accuracy can be obtained by comparison with measurements of standard gas mixtures. This level of precision is similar to or better than that obtainable by the usual high-precision analyses currently used at background clean air monitoring stations, but is available from a single FTIR instrument.

Natural variations in the \textsuperscript{13}C/\textsuperscript{12}C ratio in atmospheric CO\textsubscript{2} are a valuable diagnostic for deciphering the atmospheric budget of CO\textsubscript{2}, because individual source and sink processes fractionate the isotopes differently and leave a characteristic isotopic “signature” in the resultant CO\textsubscript{2}.\textsuperscript{[87]} The spectrum of \textsuperscript{13}CO\textsubscript{2} is partially resolved from that of \textsuperscript{12}CO\textsubscript{2} at 1 cm\textsuperscript{-1} resolution and provides the basis for FTIR measurements of the \textsuperscript{13}C/\textsuperscript{12}C isotopic ratio. With the same experimental configuration as described above, we routinely obtain precision for the \textsuperscript{13}CO\textsubscript{2}/\textsuperscript{12}CO\textsubscript{2} ratio of better than 0.02%,\textsuperscript{[86,88]} which is sufficient to resolve important natural variability. We are also developing methods for other isotopic ratios in trace gases using high-resolution FTIR spectrometry, such as \textsuperscript{18}O/\textsuperscript{17}O in CO\textsubscript{2} and CO and \textsuperscript{15}N/\textsuperscript{14}N in N\textsubscript{2}O; we currently obtain a precision of the order of 0.1–0.2%.\textsuperscript{[88]}

6.4 Measurements of Trace Gas Fluxes by Fourier Transform Infrared Spectrometry and Micrometeorological Techniques

Knowledge of the rates of exchange of trace gases such as CO\textsubscript{2}, CO, CH\textsubscript{4} and N\textsubscript{2}O between the earth’s surface and the atmosphere in different environments is also crucial in assessing global trace gas budgets. The flux-gradient technique for measuring trace gas exchange fluxes requires high-precision measurements of the vertical profile of mixing ratios in the lowest few meters of the atmosphere, combined with measurements of profiles of temperature, water vapor, wind speed and direction. To measure typical fluxes in agricultural environments, analytical precision of the order of 0.2% is required in an in situ measurement in a few minutes. We have applied high-precision in situ FTIR analysis for this purpose in a number of field campaigns.

We use equipment similar to that described for high-precision concentration measurements (section 6.3), except that a dual-beam configuration with two matched multipass cells based on a Bomem MB100 spectrometer is used.\textsuperscript{[88–93]} This design effectively doubles the rate at which samples can be measured, since one sample can be analyzed by the spectrometer while the other is being filled with the next sample to be measured, and the duty cycle of the spectrometer is maximized. In a typical experiment, air samples drawn through continuous tubing from several heights above ground on a mast are analyzed sequentially in a 2-min measurement cycle so that a complete vertical profile is determined every 20–30 min. The trace gas flux is then determined for each 30-min period from the diffusion equation and the vertical gradient of trace gas concentration (Equation 15):

\[
\text{Flux} = K \frac{\partial c}{\partial z}
\]  

where K is the eddy diffusion coefficient (determined concurrently by micrometeorological techniques) and \( \frac{\partial c}{\partial z} \) is the vertical gradient of trace gas concentration. Using high-precision FTIR trace gas analysis we can resolve small gradients of <1 ppmv CO\textsubscript{2}, 5 ppbv CH\textsubscript{4},
0.2 ppbv N_2O, 0.5 ppbv CO and 4 ppbv NH_3 per meter in the required measurement times of a few minutes.

### 6.5 Open-path and Extractive Measurements of Biomass Burning and Combustion Gases

Biomass burning is a major contributor of many trace gases to the atmosphere. Open-path FTIR measurements are well suited to the analysis of smoke and plumes from biomass burning because they are applicable to a wide range of species and sufficiently sensitive for such relatively concentrated samples. Since many compounds in smoke are reactive, labile or otherwise difficult to sample, the noninvasive advantage of FTIR monitoring also applies. In 1989 we made a series of open-path FTIR analyses through smoke from prescribed burning of open rangeland and forest logging waste using a trailer-mounted bistatic system at 0.12 cm

paths from 30 to 100 m. We were able to quantify a number of compounds simultaneously in the smoke, including CO_2, CO, CH_4, CH_2O, N_2O, NO, NO_2 and NH_3. The nitrogen-containing species in particular are difficult to measure together by other techniques, and these measurements provided a good overview of the fuel nitrogen budget during combustion.

We also used the spectrometer over a simple folded 3-m open path across the stack of a large-scale combustion research laboratory to investigate the combustion products from a range of biomass fuels. Concentrations in the stack are much higher than in field measurements and a wide range of species has been identified despite the shorter path. The technique has since been further developed to include a dedicated FTIR spectrometer and an open-path White cell with a 1.5-m base path. Of particular interest from this work has been the identification and quantification of many oxygenated organic molecules which play an important role in photochemistry and ozone formation in the smoke plume downwind of the combustion source. The spectrometer and White cell have also been installed in an aircraft and used to grab and analyze samples from flights through smoke plumes from wild and prescribed forest fires.

Canister samples of smoke collected from biomass burning sources can also be conveniently analyzed for CO_2, CO, CH_4, N_2O and other minor species in a single measurement by FTIR spectroscopy in the laboratory. We have analyzed a large number of samples from Australian biomass burning studies with this technique, with samples collected in pre-evacuated 600-mL glass flasks. After drying with MgClO_4, the samples were analyzed on a Bomem DA3 spectrometer at 0.2 cm

resolution in a 5.6-m White cell.

FTIR spectrometry is also used extensively in the analysis of stack gases from industrial incinerators and power plants, where again the nonintrusive and multicomponent advantages can be exploited. In general, measurements can be made either directly in an open path across the stack, or extractively, where stack gases are sampled into a measurement cell in the FTIR spectrometer. In the latter case, heated lines and cells must be used or the sample diluted to avoid condensation of the hot gases (especially water vapor) on cooler surfaces. A detailed treatment is beyond the scope of this article. Mao et al. provide a detailed example.

### 6.6 Volcanic Emissions

Volcanoes are a significant source of many gases (such as CO_2, CO, SO_2, OCS, HF and HCl) to the atmosphere, and analysis of the plume gases from active volcanoes is also an important tool in assessing volcanic activity and eruptive state. Clearly, in situ sampling is logistically difficult and often dangerous, and remote measurements are desirable if possible. Several authors have described FTIR open-path remote measurements in the plumes of active volcanoes by a number of methods. Francis et al., made bistatic measurements over paths of 500–1900 m across active fumaroles and craters using a conventional globar source. They measured emissions of HCl, SO_2, SiF_4 and other gases and found good correlations between different species and plume temperature. They also made measurements using naturally occurring areas of hot ground surface as a natural IR source, as did Mori and Notsu. Fateley et al. made similar measurements and also emission measurements of hot plumes ratioed to the colder sky background. Francis et al. later made further measurements by solar occultation, where the FTIR spectrometer was located far from the target volcanic plume so that the direct solar beam passed through the plume. The sun was manually tracked into the spectrometer to provide an absorption spectrum, allowing detection of HF in addition to other molecules as above. In a different approach, McGee and Gerlach used an aircraft-mounted FTIR spectrometer with White cell to collect and analyze in situ samples from traversals of the plume from Kilauea volcano, Hawaii. Finally, Love et al. used two passive FTIR techniques at long distance to monitor the plume of an actively erupting volcano, Popocatepetl, Mexico. The spectrometer was located 17 km from the erupting volcano. For spectra below 1200 cm

, the emission from the hot plume itself was measured against the background of the colder clear sky. For spectra above 2000 cm

, scattered sunlight from high-altitude cloud was used as the radiation source. FTIR measurements of volcanic emissions have been reviewed by Oppenheimer et al.
6.7 Remote Sensing by Solar Fourier Transform Infrared Spectrometry

The sun is a very good radiation source, with an effective blackbody temperature of 5800 K and an angular size large enough to overfill the field of view of a typical FTIR optical system. When spectra of the sun are recorded through the atmosphere, rich spectra with high S/Ns and high spectral resolution can be obtained in a few seconds to minutes. Remote sensing of atmospheric composition by solar IR spectroscopy is routinely carried out from the ground, aircraft, high-altitude balloons and from space. Beer\(^\text{108}\) and Rao and Weber\(^\text{109}\) provide a detailed introduction to FTIR remote sensing and atmospheric spectrometry.

Atmospheric pressure drops off approximately exponentially with altitude; the total vertical atmospheric column at sea level is equivalent to that of a single layer 8 km thick at 1 atm pressure and 273 K, and increases approximately as the secant of the solar zenith angle. In the lower atmosphere individual spectral lines are predominantly pressure broadened with near-Lorentzian lineshapes and pressure-dependent widths, whereas in the upper atmosphere pressure broadening is dominated by Doppler broadening and the lineshapes are predominantly Gaussian and dependent on temperature but not pressure. Thus atmospheric solar spectra display lineshapes that depend on the altitude range of the light path and vertical distribution of the absorber molecules in the atmosphere. Figure 7 illustrates this effect, with a portion of the solar spectrum measured at 0.004 cm\(^{-1}\) resolution near 1150 cm\(^{-1}\). The broader lines are due to N\(_2\)O, which resides predominantly in the troposphere (<15-km altitude), and the narrow lines are due to ozone, most of which is in the stratosphere (>20 km). Quantitative analysis of solar FTIR spectra is normally carried out by NLLS fitting of calculated spectra (see, for example, sections 5.6 and 5.8) to measured spectra. The equivalent width of each line (i.e. the area under the line) is related to the total column amount of the absorbing species, and detailed analysis of the lineshape provides a method for retrieving limited information on the vertical distribution.\(^\text{45,110,111}\)

For ground-based solar FTIR spectrometry, a sun tracker is used to image the solar disk on to the entrance aperture of the FTIR spectrometer, which normally has high resolution (0.004 cm\(^{-1}\)) to resolve the lineshapes of stratospheric gases and provide some altitude resolution. MCT detectors are normally used below 1800 cm\(^{-1}\) and InSb detectors above 1800 cm\(^{-1}\), with optical bandpass filters usually required to reduce the total flux on the detector and avoid detector saturation. Single scans typically provide S/N of 200–1000 at high resolution. Despite its much lower intensity as a radiation source, the moon has also been used as a source for atmospheric measurements in the high Arctic.\(^\text{112}\) A global network of ground-based solar FTIR stations operates as part of the network for detection of stratospheric change (NDSC).\(^\text{113}\) Atmospheric constituents that can be detected include ozone (four different isotopomers), major chlorine and fluorine species (HCl, ClONO\(_2\), HF and COF\(_2\)), species related to ozone destruction including ClO, HNO\(_3\), NO, NO\(_2\), halocarbons such as CFC-11, CFC-12 and CFC-22, major greenhouse gases such as CO\(_2\), H\(_2\)O, HDO, CH\(_4\) and N\(_2\)O and a number of other mainly tropospheric species including C\(_2\)H\(_2\), C\(_2\)H\(_4\), C\(_2\)H\(_6\), CO, H\(_2\)CO, HCN, HO\(_2\)NO\(_2\), NH\(_3\), OCS and SO\(_2\). For further details we refer readers to a sample of publications from some of the NDSC groups.\(^\text{110,111,114–121}\)

Ground-based solar spectroscopy can be carried out from any altitude but is best from higher altitudes to reduce absorption by water vapor (which is heavily concentrated near the ground) and undesirable effects of pollution in the atmospheric boundary layer. Thus two of the best sites are at Mauna Loa in Hawaii (3400 m above sea level)\(^\text{115}\) and the Jungfraujoch in Switzerland (3580 m above sea level).\(^\text{118}\) Solar FTIR spectrometry from aircraft\(^\text{122–124}\) and balloons\(^\text{125–127}\) provides more detailed data on the upper atmosphere. For spectra collected with the sun above the observation altitude (zenith angles < 90\(^\circ\)), the principles are the same as for ground-based measurements. For spectra collected near sunrise or sunset with the solar zenith angle below the observation altitude (>90\(^\circ\)), absorption is dominated by the atmospheric layers nearest the tangent altitude of the solar beam. An “onion-peeling” technique can then be used to determine vertical profiles, in which spectra are measured as the sun sets (or rises), and the spectra of upper layers are analyzed first and the analyses successively subtracted from those of the lower layers.

Figure 7 Small section of a solar FTIR absorption spectrum near 1150 cm\(^{-1}\) illustrating the lineshape dependence on the vertical distribution of the absorber. The three broader lines are due to N\(_2\)O, which resides predominantly in the troposphere, and the narrow lines are due to ozone, most of which is in the stratosphere.
Measurements can be made from up to 40-km altitude with large stratospheric balloons.

Satellite-borne FTIR solar absorption spectrometers effectively observe from above the entire atmosphere and can provide pseudo-global coverage of atmospheric composition. For example, the ATMOS spectrometer, which made several flights on the Space Shuttle in the 1980s and 1990s, has provided a large body of atmospheric composition data with broad geographic coverage. ATMOS typically measures 100 spectra at 0.017 cm\(^{-1}\) resolution (60 cm OPD) during each 4-min solar occultation from the 300-km altitude orbit of the Space Shuttle; in the November 1994 mission, it measured 190 such occultations. For an overview and further details, see Gunson et al.\(^{(128)}\) and following papers in a special issue of \textit{Geophysical Research Letters}. A number of other satellite-borne FTIR spectrometers have already been flown, with many more planned.

### 6.8 Infrared Emission Spectrometry of Plumes and Stack Emissions

Sources of hot gases such as stack plumes and flares emit radiation above the ambient background level, allowing a passive, single-ended method of remote FTIR trace gas detection where no separate IR source is required. Early measurements of stack emission were made with the ROSE system described in section 6.2.\(^{(69)}\) Haus et al.\(^{(74)}\) have more recently described this type of measurement, shown schematically in Figure 8.

The hot plume is viewed by the FTIR spectrometer, typically through a telescope to restrict the field of view. The total intensity may be thought of as (1) the background intensity \(I_b\) transmitted through the plume and foreground atmosphere (transmittance \(t_p\) and \(t_f\), respectively) plus (2) the plume emission \(I_p\), transmitted through the foreground atmosphere, plus (3) any emission \(I_f\) from the foreground atmosphere. The plume emission term \(I_p\) is the product of the blackbody or Planck function \(B(\bar{v}, T_p)\) at the temperature \(T_p\) of the plume and the emissivity \((1 - t_p)\) of the plume. Thus (Equation 16):

\[
I = I_b t_p I_f + I_p t_f + I_f
\]

All terms in Equation (16) are implicitly dependent on frequency, \(\bar{v}\). Analysis of the spectrum \(I(\bar{v})\) requires calculation of the atmospheric transmittance and plume emission spectra and least squares fitting to the measured spectra. The contribution from the background term \(I_b\) can be measured by recording the spectrum with the telescope pointed beside the plume, and the contribution removed from the calculation. Haus et al.\(^{(74)}\) described examples of the analysis of stack emissions from power plant plumes for a range of gases, for example, H\(_2\)O, CO\(_2\), CO, CH\(_4\), N\(_2\)O, NO, NO\(_2\), SO\(_2\), NH\(_3\), HCl and CH\(_3\)O. While this technique is very attractive for its true remote sensing characteristic, quantitative analysis of the spectra is more complex, and both accuracy and detection limits are inferior to those achievable by in situ or cross-stack measurements if these can be made.

### 6.9 Cryogenic Sampling: Matrix Isolation

Finally, we mention one further but somewhat different approach to atmospheric analysis by FTIR spectrometry, in which the air sample is collected and analyzed cryogenically at liquid nitrogen temperature, 77 K. The technique is described in detail elsewhere,\(^{(129,130)}\) and we give here only a brief overview. After water vapor has been removed from an air sample, the main condensible component at 77 K is CO\(_2\), which forms a matrix in which all other trace gases are embedded. This CO\(_2\) is deposited as a matrix on a flat mirror or on the inner surface of an integrating sphere\(^{(15)}\) at 77 K, and its absorption spectrum recorded for analysis of the trace gas composition of the sample. The technique is applicable to a wide range of species since virtually all trace gases are condensable, including labile or reactive species, which are effectively trapped and stable in the cold matrix. There is an effective preconcentration in the CO\(_2\) that leads to low detection limits, in the pptv (pmol mol\(^{-1}\)) range in some cases. The technique has been used to detect and quantify phosgene (COCl\(_2\)) in samples collected from an aircraft in the upper troposphere and lower stratosphere\(^{(131)}\) and to analyze for a wide range of volatile compounds in smoke samples from natural biomass burning.\(^{(98)}\)

The acronym LIDAR stands for light detection and ranging, an optical analog of RADAR (radio detection and ranging). The conventional version of LIDAR requires a laser transmitter to launch short pulses of coherent light, which are scattered from atmospheric targets of interest back to an optical receiver, with a time delay that is determined by the range of the target. Optical phenomena in the Earth's atmosphere (e.g. Rayleigh scattering, Raman scattering, Mie scattering, refraction, and resonant absorption) contribute to the amplitude of optical signals returning to the receiver and their characteristic wavelength dependence allows us to measure the concentration and velocity distributions of different atmospheric molecules and aerosol particles. LIDAR backscattering in the infrared (IR) region, on which this article concentrates, is well suited to detecting aerosols (as in clouds or industrial particulate emissions). IR DIAL (differential absorption LIDAR), a variant in which two wavelengths are used simultaneously to separate resonant molecular signals from background, enables most molecular species to be monitored by means of their IR absorption spectra. A closely related approach comprises long-path IR laser absorption, with retro-reflection from a topographic target (e.g. a strategically located mirror); this sacrifices optical range information but gains sensitivity because it integrates over all molecules in the optical column between the transmitter/receiver and the reflector. Such techniques are vitally dependent on pulsed IR laser technology.

1 INTRODUCTION

This article is concerned with laser-based atmospheric sensing in the IR region (arbitrarily defined here by the wavelength range ~0.7–20 µm, or ~14 000–500 cm⁻¹ in wavenumber units). Atmospheric sensing by IR LIDAR relies on two key factors: the strength of IR scattering from aerosols and particulates (relative to that from molecules) and the amenability of most molecular species to be monitored by means of their IR absorption spectra. These factors are vital to the general range-resolved form of IR DIAL, which depends on elastic scattering from atmospheric aerosols (to act as a "distributed mirror") and on characteristic vibration–rotation absorption spectra as signatures of specific molecules in the atmosphere (e.g. water, methane, ozone, and various pollutant species). The latter attribute also enables retro-reflected long-path IR laser absorption which entails a trade-off between range resolution and sensitivity. Such IR laser-based techniques contrast with atmospheric sensing in the visible and ultraviolet (UV) regions, where the optical processes involved arise predominantly from electronic properties of molecules: Rayleigh and Raman scattering, electronic absorption, and fluorescence.

Several atmospheric sensing strategies involving IR LIDAR and related techniques are shown in Figure 1(a–c). These will be discussed in more detail at appropriate stages of this article. In early literature, terms such as "optical RADAR" and "laser RADAR" were synonymous with "LIDAR", in view of its range-resolution capabilities. However, LIDAR tends now to embrace techniques that monitor an optically defined column of the atmosphere, as in Figure 1(b) and (c), in addition to true range-resolved LIDAR. That broader view of IR LIDAR will be adopted in this article.

Reviews of LIDAR-based atmospheric sensing usually concentrate either on particular detection techniques (e.g.
DIAL, Raman LIDAR or laser heterodyne radiometry) or on a particular class of atmospheric phenomena (such as aerosols, particulates, or pollutant emissions), rather than on a single spectral region. This article is concerned with LIDAR-based atmospheric monitoring in the IR region (arbitrarily defined here by the wavelength range ~0.7–20 µm, or ~14 000–500 cm⁻¹ in wavenumber units). Nevertheless, IR LIDAR cannot be treated in isolation from complementary LIDAR techniques using visible or UV laser radiation, so comparisons will be made where appropriate. The article aims to integrate principles of IR LIDAR instrumentation and its applications to atmospheric sensing.

Some of those applications are treated in this Introduction. Others are classified in section 3, according to the forms of coherent light source employed, notably fixed-wavelength solid-state lasers (e.g. Nd:YAG (yttrium aluminum garnet) lasers at 1.06µm), line-tunable gas lasers (e.g. CO₂ lasers at 9–11 µm), tunable solid-state lasers (e.g. Ti³⁺:Al₂O₃ lasers at 0.7–1 µm, alexandrite at 0.7–0.8 µm, and various semiconductor diode lasers), and nonlinear-optical wavelength converters, such as Raman shifters, difference-frequency generators, and optical parametric oscillators (OPOs).

1.1 Historical Perspectives

Interactions between light and the Earth’s atmosphere produce many natural spectacles, such as rainbows, sunsets, blue skies, and clouds. In a sense, therefore, there is not much new about using optical phenomena to monitor and predict atmospheric conditions, as this probably comprised one of the earliest forms of human observation and inference. During the last few decades, however, natural phenomena arising from sunlight have been supplemented by using artificial light sources (notably lasers) to probe the atmosphere and yield meteorological and pollution-related information in unprecedented detail. In the same period, our knowledge of atmospheric chemistry and physics has been much enhanced by the analytical capability of optical and spectroscopic sensing.

For at least half a century, it has been well understood that a short pulse of light could be used to locate and map atmospheric objects such as cloud ceilings. This approach, for which the acronym “LIDAR” was coined as early as 1953, entails timing the interval between the light pulse from an optical transmitter (e.g. a powerful flashlamp) and a pulsed return signal, detected by an optical receiver. With the advent of pulsed ruby lasers in 1960, LIDAR advanced rapidly; no doubt exceeding expectations of its early pioneers from the searchlight era. Developments in laser technology have since then continued to drive many of the key advances in LIDAR methodology.

DIAL is an important differential spectroscopic adjunct to LIDAR; two wavelengths of pulsed light are used simultaneously to detect signals from an atmospheric species of interest in the presence of unwanted background signals. Long-path laser absorption, where range resolution is exchanged for sensitivity, is closely related to DIAL. Other related techniques include DOAS (differential optical absorption spectroscopy, usually recorded by dispersing broadband ultraviolet/visible (UV/VIS) light) and DISC (differential scattering).

![Figure 1](image-url)
IR LIDAR is well served by pulsed IR lasers, of which Nd: YAG and carbon dioxide (CO\textsubscript{2}) lasers have been most prominent, superseding earlier ruby lasers\cite{8,10,14} operating at ~694 nm. Nd: YAG lasers have a solid-state gain medium\cite{14}, in which neodymium ions (Nd\textsuperscript{3+}) in a YAG (Y\textsubscript{3}Al\textsubscript{5}O\textsubscript{12}) host, are flashlamp- or diode-pumped to yield high-quality laser output at 1.064 µm (or its harmonics at 532, 355 or 266 nm for UV/VIS LIDAR applications). The CO\textsubscript{2} laser is a discharge-excited gas laser that is line tunable over rotation–vibration bands of the IR emission spectrum of CO\textsubscript{2}, in the range 9–11 µm\cite{18–21}. Apart from these two “workhorse” lasers for IR LIDAR, there are other useful lasers and nonlinear-optical devices (such as OPOs)\cite{22} to be discussed later in this article. Some are continuously tunable and many are adaptable for field-based sensing. A key theme of this article concerns advances in IR laser technology that have steered the progress of IR LIDAR over the last 30 years and that are set to continue to do so in the future.

1.2 Sources of Information

IR LIDAR is a mature technological field, well served by many excellent literature resources. The following brief bibliographic survey is not intended to be comprehensive, but rather to provide a broad foundation and an indicative bibliography. Measures has produced a major textbook\cite{5} and an edited work,\cite{4} Grant et al. have generated several useful reviews\cite{6,23,24} and a compilation of research papers,\cite{9} as well as an ongoing electronic LIDAR bibliography.\cite{25} Notable review collections include those edited by Hinkley,\cite{26} Killinger and Mooradian,\cite{27} and Sigrist.\cite{5} Various other early review articles\cite{28–33} give useful perspectives on the subject. The reader is also referred to authoritative reference books on lasers,\cite{10–14} laser spectroscopy,\cite{34,35} and applications of quantum electronics and nonlinear optics.\cite{36–38}.

1.3 The Earth’s Atmosphere

The objective of IR LIDAR methodology reviewed in this article is the Earth’s atmosphere: its composition, structure, dynamics, and chemistry.\cite{2,39} These factors influence problems such as global warming, stratospheric ozone depletion, and photochemical smog formation. Meteorology drives much of the interest in LIDAR, which is able to provide information on aerosols, atmospheric chemistry, clouds, winds, and pollution. In the case of aerosols,\cite{40} LIDAR can measure and map their characteristic spatial, size and shape distributions, as well as their chemical and physical composition. The temperature-inversion mixing layer that traps urban pollution can be monitored by ground-based LIDAR, as can localized plumes of particulates and chemicals emitted from industrial sites. Airborne LIDAR platforms can cover large areas quickly, e.g. to monitor migration of aerosols across international boundaries or to study the effects of major volcanic eruptions.

Meteorological parameters of the Earth’s troposphere and stratosphere that can be measured by various forms of LIDAR include wind velocities, temperature, pressure, density, and humidity.\cite{6} LIDAR measurements in the IR region do not generally suffice to obtain all of these measured parameters. As will become apparent in sections 1.4 and 1.5, two or more IR, visible, or UV laser wavelengths are often used to determine different atmospheric properties and to separate the distinct signals from molecules and aerosols. IR LIDAR (particularly DIAL)\cite{15,16} is a useful way to monitor the molecular composition of the atmosphere, by means of spectroscopic signatures contained in vibration–rotation bands of particular molecules. Atmospheric concentration profiles of water and ozone are of particular interest.

1.4 Nonresonant Optical Scattering Processes

Various forms of interaction between light and matter are at the heart of optical remote sensing methods such as LIDAR. Relevant atmospheric sensing schemes have already been depicted schematically in Figure 1(a–c). In this section, we consider “nonresonant” processes, which do not require the laser light to be tuned to a specific resonant wavelength. Resonant optical processes will be considered separately in section 1.5.

As already stated, this article emphasises phenomena that are observable with IR light sources and are therefore not visible by the human eye (400–700 nm). Even in the natural world, however, the refraction of sunlight from water droplets gives rise to IR rainbows which can be photographed with IR-sensitive film at 800–900 nm.\cite{1} Likewise, there are advantages for LIDAR in accessing the IR region, as well as the visible and UV regions.

Two forms of quasi-elastic light scattering are important here: Rayleigh scattering (from individual molecules) and Mie scattering (from particles that are generally of size comparable to the wavelength of the light itself).\cite{41,42} Neither process involves a spectroscopic resonance, so that the choice of laser wavelength \( \lambda \) is not critical or selective for particular scattering species (note, however, that scattering cross-sections at wavelengths close to resonance may be enhanced markedly relative to those off resonance; resonance fluorescence occurs when the laser wavelength is exactly resonant).

The \( \lambda^{-4} \) wavelength dependence of Rayleigh scattering causes it to be relatively unimportant for laser wavelengths longer than ~1 µm and therefore only barely relevant to the IR LIDAR topic of this article. Clear skies...
appear blue and sunsets red because blue light is Rayleigh scattered more strongly than red light.\(^{(1)}\)

Mie scattering\(^{(41,42)}\) from particles (e.g. aerosols, clouds, ice particles, dust) remains of critical interest in the context of IR LIDAR.\(^{(46)}\) The original theory, which dates back to work published in 1908 by Gustav Mie (and independently, in 1909, by Peter Debye),\(^{(43)}\) refers only to spherical particles and their characteristic angle and polarization dependences. Mie’s theory can be adapted to the case of “real-life” nonspherical particles.\(^{(44,45)}\) The wavelength dependence of Mie scattering from aerosols and other particles is more complicated than the simple \(\lambda^{-4}\) law for Rayleigh scattering from small molecules. It usually varies as \(\lambda^{-3}\), where \(0 < \delta < 3\), with \(\delta\) smaller for bigger particles; if \(\lambda\) greatly exceeds the particle diameter then the scattering will be weak, but it will increase markedly as \(\lambda\) becomes equal to, or smaller than, the particle diameter. There is therefore a trade-off between particle diameter in the atmospheric target and the wavelength, efficiency, and availability of laser. Clouds often appear white because cloud aerosols are relatively large and Mie scatter visible sunlight with a much less pronounced wavelength dependence than for Rayleigh scattering.\(^{(1)}\)

Many aerosol scattering measurements are made in the spectral region 0.5–1.5 \(\mu\)m, so that Nd: YAG lasers (at 1.06 \(\mu\)m) are useful here. CO\(_2\) lasers (at 10.6 or 9.11 \(\mu\)m) are also widely used, with their relatively weak scattering compensated by the high pulse energy and electrical efficiency that is attainable with a CO\(_2\) laser, combined with the atmosphere’s relatively high transparency at 9–11 \(\mu\)m. The reliable application of such a CO\(_2\) laser system to aerosol scattering requires careful calibration of scattering efficiency.\(^{(40)}\)

Multimwavelength LIDAR systems are sometimes used to determine variations between size distributions of different aerosol types.\(^{(40)}\) Most of these use UV and visible laser wavelengths but one\(^{(47)}\) in the IR LIDAR context has employed a Ti\(^{3+}\): Al\(_2\)O\(_3\) laser to generate radiation at 750 and 850 nm and also Nd: YAG laser harmonics; this system has allowed polarization-sensitive measurements of aerosol size distribution in polar stratospheric clouds and the Mount Pinatubo volcanic eruption.\(^{(40)}\)

We refer to Rayleigh and Mie scattering as “quasi-elastic” since each is sensitive to motion of the molecules or particles along the direction of the laser beam, yielding a Doppler shift \(\Delta v_D\) of the 180°-backscattered radiation relative to the frequency \(v_L\) of the incident laser light (Equation 1):

\[
\Delta v_D = 2v_L \frac{v}{c} \quad (1)
\]

where \(v\) is the particle velocity along the laser beam and \(c\) is the speed of light; such differences between laser wavelength \(\lambda_L\) and received wavelength \(\lambda\) are implicit in Figure 1(a).

Mie scattering from atmospheric aerosol particles, moving with the air mass, displays small Doppler shifts that yield wind speed profiles. CO\(_2\)-laser Doppler velocimetry LIDAR systems have achieved this objective in various applications.\(^{(6,48,49)}\) Sensing of tropospheric horizontal wind velocities from airborne and space-based Doppler LIDAR platforms receive much ongoing attention.\(^{(6,49)}\) Doppler shifts are recorded by combining the backscattered return signals (at frequency \(v_L + \Delta v_D\)) coherently with part of the outgoing laser radiation (at \(v_L\)), using a heterodyne detection system\(^{(50)}\) in which beat frequencies yield the Doppler shifts \(\Delta v_D\). Wind velocities are thereby determined to an accuracy of 1 m s\(^{-1}\).

Accompanying quasi-elastic Rayleigh scattering is its inelastic counterpart, Raman scattering. This too is a nonresonant molecular process, in the sense that it is a slowly varying function of laser wavelength \(\lambda_L\). However, Raman scattering carries information about the molecular species from which the scattering emanates, with characteristic Raman shifts \(\Delta v_R\) separating the frequency \(v_R\) of scattered radiation from the exciting laser frequency \(v_L\).\(^{(51,52)}\) (Equation 2):

\[
\Delta v_R = v_L - v_R \quad (2)
\]

The strongest Raman scattering is for positive values of \(\Delta v_R\) (i.e. \(\lambda_R > \lambda_L\)) and is known as Stokes scattering. Raman scattering, like Rayleigh scattering, has a \(\lambda^{-4}\) wavelength dependence and so is more efficiently excited by UV and visible lasers than by the IR lasers on which this article concentrates. However, Raman LIDAR\(^{(53-55)}\) is an important adjunct to IR LIDAR techniques used to measure molecular species and concentrations in the atmosphere. Its mode of detection is similar to that depicted in Figure 1(a), except that Raman scattering is usually excited in the UV or visible region, with received wavelength \(\lambda = \lambda_R\), and arises from molecules rather than aerosol particles. Raman LIDAR is particularly useful for detecting water vapor (for which \(\Delta v_R \approx 3652\) cm\(^{-1}\));\(^{(55)}\) see section 5 for aspects of recent progress. It can also monitor homonuclear diatomic species, such as N\(_2\) (\(\Delta v_R \approx 2331\) cm\(^{-1}\)), which has no IR-active vibrational mode and is therefore not amenable to IR LIDAR; this approach can measure temperature and density profiles of N\(_2\) in the upper troposphere and stratosphere.\(^{(55)}\)

### 1.5 Resonant Optical Processes

The preceding section covered a variety of nonresonant optical scattering processes (notably Rayleigh, Raman, and Mie scattering) in which the scattering cross-section is generally a slowly varying function of laser wavelength and depends on the real part of the optical susceptibility.
of the scattering medium.\(^{56}\) In this sense, Rayleigh scattering is closely related to refraction and normal dispersion in a dilute optical medium. In regions of anomalous dispersion, however, the imaginary part of the (complex) optical susceptibility becomes significant and rapid variations of scattering cross-section occur as the laser wavelength is varied. More significantly, the phenomenon of optical absorption then arises, yielding a rich source of spectroscopic information and a principal area of interest in IR LIDAR.

Molecular absorption spectra provide a characteristic signature that is useful for identification and analytical determination. UV and visible absorption spectra (which are beyond the scope of this article) involve transitions to excited molecular electronic states. For instance, stratospheric ozone (O\(_3\)) has strong UV absorption bands that provide a protective filter against harmful solar UV-B radiation (280–320 nm); its depletion has created the infamous “ozone hole”\(^{59}\). The same UV absorption bands can enable O\(_3\) to be detected and mapped using, for instance, XeCl excimer lasers operating at 307.9 nm\(^{56}\).

In the contrasting context of IR LIDAR, the key transitions are between quantized vibrational states associated with normal modes of molecular vibration. The theory and practice of IR absorption spectroscopy are established\(^{57–59}\) as are correlations between such spectra and molecular structure.\(^{52}\) Heliostatically tracked IR spectra of solar radiation transmitted through the atmosphere, as shown in the upper part of Figure 1(c), are used traditionally to characterize atmospheric constituents\(^{28,59}\) and can be monitored with high sensitivity by laser heterodyne radiometry.\(^{60}\) either airborne or ground-based. IR LIDAR absorption spectroscopy in general, and DIAL in particular, will be discussed later in this article. In the meantime, we note that CO\(_2\) lasers have a fortuitous coincidence at \(\sim 9.6\) \(\mu\)m with a vibrational absorption band of ozone; this enables IR DIAL methods to measure trace concentrations of tropospheric O\(_3\) at a range of 1–2 km.\(^{16}\)

Fluorescence, an optical phenomenon that is effective when an atom, ion, or molecule spontaneously emits radiation from a high-energy quantum state that has been excited (e.g. by electric discharge, optical absorption, or heating); it has a finite fluorescence quantum yield that is subject to collisional quenching.

Laser-induced fluorescence (LIF) can occur either elastically (resonance fluorescence) or inelastically (with emitted wavelength \(\lambda \neq \lambda_L\)) and its LIDAR counterpart employs a detection scheme similar to that depicted in Figure 1(a). Fluorescence LIDAR\(^{61}\) can be used, for example, to study concentrations of the hydroxyl radical (OH) in the troposphere,\(^{62,63}\) but it is generally confined to UV and visible excitation. Trace alkali metal atoms in the atmosphere are particularly amenable to LIDAR monitoring by laser-induced visible or UV resonance fluorescence.\(^{15,54,64,65}\)

The intrinsically long radiative lifetime of laser-induced infrared fluorescence (LIIRF) yields a low intensity, which is further diminished by collisional quenching.\(^{66}\) Early proposals to use LIIRF for range-resolved atmospheric monitoring\(^{29,31,32,67}\) were optimistic, with traces of diatomic species such as CO and NO predicted to be detectable at a range of 100 m by high-power pulsed IR lasers. However, it was soon recognized\(^{68,69}\) that far higher sensitivity could be attained by range-resolved IR DIAL methods, with atmospheric aerosols and particulates in the atmosphere serving as distributed reflectors, as in Figure 1(a). In this IR DIAL approach, elastically backscattered laser radiation of this type is collected by the LIDAR receiver and the variation of its intensity with time is used to extract range information.\(^{3,15,24,70,71}\) Details are discussed in section 2.2.

While remote sensing by LIIRF may be impractical, a viable alternative is thermally induced infrared fluorescence (TIIRF) from hot molecules (e.g. in industrial smokestacks), as shown in the lower portion of Figure 1(c). TIIRF is measurable by passive IR laser heterodyne radiometry methods, using a laser as local oscillator tuned to a spectroscopic region that characterizes the molecules of interest.\(^{31,32,50}\) However, Fourier-transform infrared (FTIR) spectroscopy\(^{59}\) appears generally to be a more sensitive means of mid-IR radiometry.

Resonant absorption plays two key roles in IR LIDAR applications: in addition to being the source of the signal of interest, it also provides a background interference effect (along with scattering by aerosols) that attenuates the outgoing and return optical signals. Studies of atmospheric transmission therefore play an important part in optimizing and calibrating IR LIDAR measurements. There are atmospheric “windows” (relatively free of absorption by H\(_2\)O, CO\(_2\) and other minor species) in various parts of the IR region, notably 1.0–1.4, 1.6–1.8, 4.3–5.3, and 7.8–13 \(\mu\)m.\(^{15,23,24,59,72}\) An extensive compilation of atmospheric IR absorption data is available commercially in the form of the HITRAN database\(^{73}\). HITRAN simulations of atmospheric transmission match real conditions well (unless, of course, unanticipated pollutant molecules or particles are present).

Absorption coefficients for atmospheric IR LIDAR spectroscopy depend on several critical factors: \(^{24}\) pressure (which influences collisional line broadening); temperature (which controls Doppler broadening of molecular lines, as well as thermal population of molecular energy levels); and the local density of energy levels (since adjacent transitions can cause “spectral wing” overlap effects). The pressure and temperature dependences of absorption coefficients need to be measured if
Adapting previously published treatments, we present principles of both nonresonant, elastic-backscatter IR LIDAR (section 2.1) and IR DIAL (section 2.2). Details have been presented by Measures. We merely give a simplified outline as in other reviews. A serious IR LIDAR practitioner needs to dig deeper for refinements.

2 THEORY AND OPERATING PRINCIPLES

The preliminary background in section 1 covers many of the constraints on IR LIDAR system design and its optimal mode of operation. We now present principles of both nonresonant, elastic-backscatter IR LIDAR (section 2.1) and IR DIAL (section 2.2). Details have been presented by Measures. We merely give a simplified outline as in other reviews. A serious IR LIDAR practitioner needs to dig deeper for refinements.

2.1 Nonresonant Infrared LIDAR

Adapting previously published treatments, the LIDAR equation for atmospheric elastic backscatter can be presented in the simplified form shown in Equation (3):

$$\frac{P_t(R)}{P_L} = \frac{A}{R^2} \eta(\lambda_L) f(R) \frac{c t_L}{2} \times \beta(\lambda_L, R) \exp[-2\kappa(\lambda_L)R]$$

where $P_t(R)$ and $P_L$ are the optical powers (W) received by the detector and transmitted by the laser source, respectively. These two devices are assumed to be coaxially located. The factor $[A/R^2]$ is the solid angle (sr) of the collecting aperture, in terms of the receiving mirror area $A$ (m$^2$) and the distance $R$ (m) between the transmitter–receiver and the region of the atmosphere doing the backscattering. The factor $\eta(\lambda)$ allows for the optical efficiency of the receiver and detector as a function of wavelength $\lambda$, while $f(R)$ defines the overlap between the transmitted beam and the field of view of the receiver. The factor $[ct_L/2]$ represents the pathlength covered by the laser light, assumed to be a rectangular pulse of duration $t_L$ (s), at any instant; note that the time taken for the laser pulse to propagate at the speed of light $c$ (m s$^{-1}$) to range $R$ and back to the receiver is $[2R/c]$, which is usually much greater than $t_L$.

The volume backscattering coefficient $\beta(\lambda, R)$ in Equation (3) is the fractional amount of incident energy backscattered per steradian per unit atmospheric pathlength; its units are therefore m$^{-1}$ sr$^{-1}$. The coefficient

$^a$ The atmospheric attenuation coefficient $\kappa(\lambda)$ is defined in section 2.1. The values listed here are for atmospheric pressure concentration.

$^b$ The effective reflectivity is calculated$^{(33)}$ for a range resolution $\Delta R = 100$ m, an atmospheric pressure concentration, and optical scattering assumed to be isotropic. The entries for absorption refer to backward-directed fluorescence. Those for nonresonant scattering processes are related to the volume backscattering coefficient (defined in section 2.1), and those for topographic targets refer to surface reflectivity of the target.

Table 1: Forms of optical interaction involved in laser-based atmospheric sensing. [Adapted from data of Killinger and Menyuk$^{(33)}$]
\[ \beta(\lambda, R) \text{ is usually the sum of many scattering contributions from atmospheric species } j, \text{ each with } R\text{-dependent number density } N_j(R) \text{ (Equation 4):} \]

\[ \beta(\lambda_L, R) = \sum_j N_j(R) \frac{d\sigma(\lambda_L)}{d\Omega} \]

where \( [d\sigma(\lambda_L)/d\Omega] \) is the electric DISC cross-section for species \( j \) at laser wavelength \( \lambda_L \). Additional factors are needed when the scattering is inelastic (as in the Doppler LIDAR or Raman LIDAR cases briefly discussed in section 1.4), since the scattered wavelength \( \lambda \) differs from the laser wavelength \( \lambda_L \). It is also assumed in deriving Equation (3) that lateral distribution effects across the area of the laser beam at range \( R \) is negligible, that is, the laser beam is assumed to have a “top-hat” spatial profile and the scattering medium is taken to be homogeneous within that profile.

The final exponential factor in Equation (3) allows for attenuation of the outgoing and returning light by a combination of absorption and scattering with a column-average atmospheric attenuation coefficient \( \kappa(\lambda) \) (m^{-1}). The factor of 2 in the exponent \([\ldots]\) in Equation (3) arises from the two-way transmission to and from the target through the atmosphere. In the case of inelastic scattering over an inhomogeneous atmospheric column, the exponent \([\ldots]\) in Equation (3) needs to be replaced by a more elaborate form (Equation 5):

\[ -2\kappa(\lambda)R = - \int_0^R [\kappa(\lambda_L, R') + \kappa(\lambda, R')] dR' \quad (5) \]

where the coefficients \( \kappa \) are now taken to be \( R\)-dependent (as would be the case in vertical atmospheric profile studies, for instance).

Equation (3) evaluates the instantaneous optical power \( P_t(R) \) received by the detector, ratioed to the transmitted laser power \( P_t \). A more pertinent quantity is the radiative energy \( E_r(R) \) received by the detector within the response time \( \tau_d \) of the detector (Equation 6):

\[ \frac{E_r(R)}{E_L} = \frac{A}{R^2} \frac{\eta(\lambda_L)f(R)}{\kappa} \frac{c}{2} \beta(\lambda_L, R) \exp[-2\kappa(\lambda_L)R] \]

where the laser pulse energy \( E_L \) equals \( (P_t \tau_L) \) in this alternative form of LIDAR equation. The effective range resolution for such a LIDAR system is limited to (Equation 7):

\[ \Delta R = \frac{c(\tau_d + \tau_L)}{2} \]

Measures\(^3,70\) presented various refinements of LIDAR Equations (3) and (6). It should be noted that some of the factors in Equations (3) and (6), namely \( P_L, E_L, A, \eta(\lambda_L), f(R), \tau_L \text{ and } \tau_d \), are properties of the LIDAR apparatus itself whereas others, namely \( \beta(\lambda_L, R) \) and \( \kappa(\lambda_L) \), are solely dependent on the atmosphere. The former comprise a LIDAR response function that needs to be calibrated carefully, as has already been mentioned in section 1.3, in the context of the CO\(_2\) laser LIDAR.\(^{40}\)

Grant\(^{24}\) surveyed some typical LIDAR system parameters. The case of Mie scattering from aerosols in the lower atmosphere (with number densities in the range \( 10^8 – 10^{11} \text{ m}^{-3} \) and Mie scattering cross-sections up to \( 10^{-12} \text{ m}^2 \text{ sr}^{-1} \)) yields an upper limit of \( 0.1 \text{ m}^{-1} \text{ sr}^{-1} \) for \( \beta(\lambda_L, R) \). Using an Nd: YAG laser (\( \lambda_L = 1.064 \mu\text{m} \), pulse energy = 1J, pulse duration = 10ns, outgoing photons per pulse = \( 5 \times 10^{10} \)) and typical LIDAR apparatus parameters with \( \kappa = 0.11 \text{ km}^{-1} \), the calculated return signal from aerosols at a range of 1 km yields a readily detectable \( P_t/P_t = 4 \times 10^{-10} \). Other orders of magnitude are summarized in Table 1.\(^{33}\)

### 2.2 Differential Absorption LIDAR

DIAL measurements compare the atmospheric attenuation at a characteristic absorption wavelength, \( \lambda_{on} \), of a certain molecule with that at a neighboring wavelength, \( \lambda_{off} \), where the specific absorption is much lower. Absorption by the target molecule can then be separated from attenuation associated with other atmospheric species (molecules, aerosols, etc.).

Two arrangements for IR DIAL-type measurements are depicted in Figure 1(a) and (b). These are distinguished by the mode of returning the laser radiation to the optical receiver. One method – actually differential long-path laser absorption,\(^{57,58}\) rather than DIAL\(^{15,16,71}\) – uses a topographic target (e.g. the ground in the case of a downward-directed airborne laser) or a strategically located retro-reflector, as in Figure 1(b). This approach gains sensitivity by sacrificing range information and measuring only column content. The other (true) DIAL method, on which we now focus, uses elastic scattering from atmospheric aerosols and particulates and thereby preserves the range-dependent advantage of LIDAR methods.\(^{15,68,69,71}\) This range-resolved form of IR DIAL is shown schematically in Figure 1(a), with two aerosol plumes shown but only one of two laser wavelengths marked explicitly.

Our treatment of IR DIAL is guided by that of others\(^{3,15,24,70,71}\) and is based on the elastic scattering LIDAR Equation (3). Assuming that \( P_t \) and \( \tau_L \) are identical at the two wavelengths \( \lambda_{on} \) and \( \lambda_{off} \) we can evaluate the ratio of the received power signals by allowing several instrumental factors to cancel out and using the \( R\)-dependent form of attenuation coefficients \( \kappa \) that was introduced in the context of Equation (5). This
yields Equation (8):

\[
\frac{P_r(\lambda_{on}, R)}{P_r(\lambda_{off}, R)} = \frac{\eta(\lambda_{on}) \beta(\lambda_{on}, R)}{\eta(\lambda_{off}) \beta(\lambda_{off}, R)} \times \exp \left\{ -2 \int_0^R \left[ \kappa(\lambda_{on}, R') - \kappa(\lambda_{off}, R') \right] dR' \right\}
\]

(8)

It is often acceptable to assume that the difference between \(\kappa(\lambda_{on}, R)\) and \(\kappa(\lambda_{off}, R)\) arises entirely from absorption of specific target molecules and that there is no significant change in other forms of optical attenuation (from aerosol scattering or other molecular absorption). Moreover, it is also often reasonable to assume that the ratios of instrumental factors \(\eta(\lambda)\) and volume backscattering coefficients \(\beta(\lambda, R)\) are equal to unity. With these approximations (which we shall adopt tentatively), the ratio of received powers is solely dependent on the difference in optical absorption of the target species at wavelengths \(\lambda_{on}\) and \(\lambda_{off}\).

From the Beer–Lambert law, we can then simplify Equation (8) to the form Equation (9):

\[
\frac{P_r(\lambda_{on}, R)}{P_r(\lambda_{off}, R)} \approx \exp \left\{ -2 \left[ \sigma_{abs}(\lambda_{on}) - \sigma_{abs}(\lambda_{off}) \right] \int_0^R N(R') dR' \right\}
\]

(9)

where \(\sigma_{abs}(\lambda)\) is the absorption cross-section (m\(^2\) molecule\(^{-1}\)) of the molecular species of interest at wavelength \(\lambda\) and \(N(R)\) is its number density (molecule m\(^{-3}\)) at range \(R\). The molecular number density \(\overline{N}_{\Delta R}\) averaged over increment \(\Delta R = R_2 - R_1\) of the range can then be expressed in terms of the differential absorption coefficient \(\Delta \sigma_{abs} = [\sigma_{abs}(\lambda_{on}) - \sigma_{abs}(\lambda_{off})]\) according to Equation (10):

\[
\overline{N}_{\Delta R} \approx \left[ 2 \Delta R \Delta \sigma_{abs} \right]^{-1} \times \left\{ \ln \frac{P(\lambda_{on}, R_1)}{P(\lambda_{on}, R_2)} - \ln \frac{P(\lambda_{off}, R_1)}{P(\lambda_{off}, R_2)} \right\}
\]

(10)

It is evident that four independent backscattered optical power measurements are needed for each determination of number density of the particular molecular species of interest. With appropriate signal averaging, the accuracy of determination of logarithmic factor […] in Equation (10) can be typically 10% or less, but the accuracy of \(\overline{N}_{\Delta R}\) itself within a particular range interval \(\Delta R\) will depend on how well \(\Delta \sigma_{abs}\) is known. Careful laboratory experiments are needed to determine \(\Delta \sigma_{abs}\) for each molecule of interest, preferably with the same laser wavelengths, optical bandwidths, etc., as are used in actual field-based LIDAR measurements.

Differential long-path laser absorption, with topographic target or retro-reflector as in Figure 1(b), loses range resolution \(\Delta R\) but gains in sensitivity and the range \(R\) for which measurements are feasible. A relationship comparable to Equation (9), with similar approximations, yields the integrated column number density \(N_{col}\) along the path of the laser beam [Equation 11]:

\[
N_{col} \approx \left[ 2R_T \Delta \sigma_{abs} \right]^{-1} \times \left\{ \ln \left[ \frac{E(\lambda_{off}, R_T)}{E(\lambda_{on}, R_T)} \right] \right\}
\]

(11)

where \(R_T\) is the range position of the topographic target or retro-reflector and \(E(\lambda, R_T)\) are relative (not absolute) radiative energies received from the reflector at \(R_T\) by a detector whose integration period, \(\tau_d\), exceeds the laser pulse duration, \(\tau_L\). Equation (11) applies to a spectrally flat reflector (e.g. an ideal retro-reflector) but this is not always the case in the IR region (for instance, topographic targets often have different scattering efficiencies at different CO\(_2\) laser wavelengths; it is then necessary to include additional corrections).

As in section 2.1, the reader seeking a more advanced theoretical treatment of DIAL and differential long-path laser absorption is referred to other sources\(^{3,70,71}\).

### 3 INFRARED LIDAR INSTRUMENTATION

A detailed description of operating LIDAR systems is beyond the scope of this article. This section merely outlines the essential elements of standard types of transmitter/receiver system for IR LIDAR measurements of the atmosphere. Many factors influencing instrument design have already been covered in sections 1 and 2, and details of laser sources suitable for IR LIDAR are surveyed in section 4. This article concentrates on IR LIDAR, but descriptions of visible and UV LIDAR systems in the literature remain useful in terms of general layout and data processing; various reviews\(^{3,5,6,24,70,71}\) are helpful in this regard.

The basic elements of any LIDAR system are as follows: a laser transmitter operating at one or more wavelengths; an optical receiver with return wavelength discrimination and photodetector(s); and electronics and data processor. Distinctive features of IR LIDAR systems (relative to those operating in visible and UV regions) are the following: the type of laser (see section 4); the need for IR-transparent optical materials for windows, partial reflectors, etc.; the virtually exclusive use of reflective optics rather than lenses; and the special IR photodetectors used (usually less sensitive than photomultipliers). There is no essential difference in broad terms between the electronics and data processing of an IR LIDAR system, and those for visible and UV LIDAR. A typical LIDAR system directs intense pulses of laser radiation towards atmospheric targets of interest, with a portion sampled to provide a zero-time electronic
triggers. Output optics can provide some form of beam collimation, spatial and/or spectral filtering and dichroic beam splitters to combine laser beams if more than one laser is used (as in DIAL).

The radiation that returns from the atmospheric target (as discussed in sections 1 and 2) is collected by a reflective telescope and usually passes through some form of wavelength discriminator (monochromator, polychromator, interferometer, and/or set of optical filters) on its way to the photodetector(s). Narrowband spectral filters are of little or no advantage in IR LIDAR for wavelengths longer than ~3 µm, owing to thermal background noise (which can be limited by reducing the field of view of the detector using liquid-nitrogen-cooled baffles).

The transmitter and receiver can be located separately, but they are usually grouped together as in Figure 1(a) and (b), so that outgoing and return beams are virtually coaxial. Many LIDAR systems need to be mobile, either in a van or trailer or on an aircraft (or satellite), with compactness an essential design element. A stable platform is needed for the laser radiation and viewing direction of the receiving telescope to be steered towards the atmospheric region of interest, aided by a viewfinder and often with an associated video camera. Aligning the transmitter, receiver, and viewfinder of an IR LIDAR instrument is not a trivial task.

Photodetectors for IR LIDAR need to provide high sensitivity, low noise, and fast time response. A limitation for IR LIDAR is that photomultipliers cannot access wavelengths longer than ~1 µm. Beyond this limit, various high-performance IR detectors are available but they generally fail to match the high gain and low noise that photomultipliers provide in the UV/VIS region, nor can they be used in a photon-counting configuration.

IR detectors can be classified as thermal detectors (including pyroelectric detectors), photovoltaic devices (photodiodes), and photoconductors. The last two classes of detector are based on a wide range of semiconductor materials, which usually need liquid nitrogen (77 K) cooling and specially designed preamplifiers for optimal performance. There is usually a three-way performance trade-off between bandwidth (rise time), detector area, and detector noise. Popular cooled photoconductive detectors include those based on HgCdTe for the 5–13 µm region (which covers the wavelength range of CO₂ lasers) and on InSb for the near-infrared (NIR) region (1–5 µm). InGaAs photodiodes are well suited to the eye-safe IR region around 1.5 µm. Closer to the visible region, silicon avalanche photodiodes (APDs) (a solid-state counterpart of photomultipliers) are favored in some recent LIDAR applications. Vidicons, diode arrays, and CCD (charge-coupled device) cameras have revolutionized spatially resolved imaging in the visible and UV regions. However, the availability of IR-sensitive imaging devices and APDs, based on materials such as Hg(Cd, Mn)Te, is limited but nevertheless an enticing prospect for future IR remote-sensing applications.

Most LIDAR receivers rely on a transient digitizer to record the variation of signal strength as a function of time delay (which corresponds to range R in the LIDAR context). Such electronic devices and associated computer facilities have progressively improved in both performance and price. Likewise, another area of rapid growth is the computing power available to process raw LIDAR signals and for image formation and presentation of results.

The twin issues of accuracy and signal-to-noise ratio are crucial to reliable IR LIDAR measurements. Aspects are briefly mentioned here, against the background of sections 1 and 2. Calibration of the LIDAR response function is especially important for single-wavelength LIDAR backscatter measurements, but still vital in DIAL systems. It is difficult to predict transmitter/receiver overlap functions, so that it is advisable to calibrate these empirically by means of a target of known reflectivity, positioned at several locations. Measurements at short range can be complicated by non-ideal overlap factors. In DIAL measurements, the two laser beams must be identically aligned and their spatial distributions and temporal profiles must coincide to avoid a serious source of systematic error. Changes in LIDAR alignment after calibration are also a persistent problem.

The installation of large high-power Nd:YAG, CO₂, and other lasers (with associated provision of electrical power, cooling, and gas or dye handling) in mobile IR LIDAR systems is nontrivial but feasible. For further insight into state-of-the-art LIDAR instrumentation, the reader is referred to several descriptions of airborne IR LIDAR facilities deployed by the US National Aeronautics and Space Administration (NASA).

A notable recent accomplishment by NASA is the project LIDAR Atmospheric Sensing Experiment (LASE), which was able to make IR DIAL measurements of water vapor, aerosol, and cloud profiles from a high-altitude (16–21 km), extended-range aircraft in September 1995. LASE employed a Ti³⁺:Al₂O₃ laser pumped by a double-pulsed Nd:YAG laser and injection-seeded by a diode laser to operate sequentially on and off resonance with absorption lines in the 813–819-nm band of H₂O vapor. The distribution of atmospheric water vapor is of fundamental importance to weather and climate, atmospheric radiation studies, the global hydrological cycle and atmospheric chemistry. It has been a key target for IR DIAL, in the pioneering work of Schotland and in subsequent early studies and ongoing developments.
Such airborne LIDAR programs are seen as forerunners of space-based sensing. One instance is NASA’s program LIDAR In-space Technology Experiment (LITE),\(^{(82,83–85)}\) comprising a cloud and aerosol LIDAR system that was deployed in the space shuttle Discovery in September 1994. LITE employed an Nd:YAG laser to generate three wavelengths (1.064 μm, 532 nm, and 355 nm) and a 1-m diameter lightweight receiver telescope mirror; the system operated for 53 h, resulting in 40 GB of data covering 1.4 × 10\(^5\) km of ground track. These data have provided a highly detailed global view of the vertical structure of clouds and aerosols, extending from the Earth’s surface up to the middle stratosphere (~20 km), coupled to a series of concurrent airborne and ground-based LIDAR validation tests. Future plans include the USA–France collaborative project Pathfinder Instruments for Cloud and Aerosol Spaceborne Observations/Climatologie Etendue des Nuages et des Aerosols (PICASSO/CENA);\(^{(85)}\) a satellite-borne Nd:YAG LIDAR emitting at 1.064 μm and 532 nm for polarization-sensitive aerosol and cloud measurements; it is scheduled to be launched in early 2003 into a sun-synchronous 705-km circular orbit. This will measure active LIDAR measurements; it is scheduled to be launched in early 2003 into a sun-synchronous 705-km circular orbit. This will perform active LIDAR measurements, flying in formation with a second satellite that carries a suite of passive optical and spectroscopic instruments. The technological feasibility of putting an 815-nm water-vapor IR DIAL instrument into space has been discussed.\(^{(82,87)}\)

4 COHERENT LIGHT SOURCES FOR INFRARED LIDAR APPLICATIONS

This section surveys lasers and nonlinear-optical instruments suited to IR LIDAR applications. Pulsed coherent IR sources (with attributes needed for range-resolved sensing) are featured, but mention is also made of shorter wavelength coherent sources such as tunable dye lasers (since dye laser radiation can be nonlinear-optically downconverted into the mid-IR region and some dyes operate in the NIR region). Likewise, continuous-wave (CW) IR lasers are not excluded, as they are useful for optical heterodyne Doppler velocimetry and long-path laser absorption. Moreover, narrowband CW devices, such as a semiconductor tunable diode laser (TDL), can act either as local oscillators in laser heterodyne systems or as wavelength-control devices in higher-power coherent sources entailing pulse amplification or injection seeding.

Eye safety\(^{(89)}\) is an important issue in designing lasers for atmospheric sensing,\(^{(6)}\) notably with regard to high-power pulsed solid-state lasers operating in the UV, visible or NIR regions.\(^{(14)}\) Wavelengths longer than 1.4 μm are considered to be eye-safe,\(^{(90)}\) which partly accounts for the acceptability of CO\(_2\) lasers (9–11 μm) as sources for IR LIDAR. There is much interest in high-power pulsed coherent sources in the vicinity of 1.5–2.5 μm, either by nonlinear-optical means\(^{(80,90)}\) or by using new solid-state laser materials.\(^{(14,49,91–93)}\)

4.1 Fixed-wavelength Lasers

Fixed-wavelength pulsed solid-state IR lasers have long been central to LIDAR instruments, such as those recording Mie scattering from aerosols. Ruby lasers,\(^{(8,10,14,94)}\) flashlamp-pumped devices operating at ~694 nm, were used almost exclusively in pathfinding applications of the mid-1960s.\(^{(6)}\) Schotland’s original DIAL studies of atmospheric water vapor\(^{(84)}\) used a temperature-tuned ruby laser. Laser-grade ruby (Cr\(^{3+}\); Al\(_2\)O\(_3\)) comprises sapphire (Al\(_2\)O\(_3\)) in which a small fraction of Al\(^{3+}\) ions are replaced (“doped”) by Cr\(^{3+}\) ions. Its tuning curve in the range 200–300 K is given by Equation (12).\(^{(14)}\)

\[
\lambda(T)(\text{nm}) = 694.325 + 0.068(T - 293) \tag{12}
\]

This enables a ruby laser’s wavelength to be varied from 694.3 nm (at ~300 K, with line width ~11 cm\(^{-1}\)) to 693.4 nm (cooled by liquid nitrogen at 77 K, with line width ~0.15 cm\(^{-1}\)).

Ruby lasers have been largely superseded in most applications by other forms of solid-state IR laser, of which the most commonly used is the Nd: YAG laser,\(^{(14)}\) first demonstrated in 1964.\(^{(95)}\) The Nd: YAG gain medium comprises a Nd\(^{3+}\)-doped YAG (Y\(_3\)Al\(_5\)O\(_12\)) crystal lattice with ~1% of the Y\(^{3+}\) sites occupied by neodymium ions (Nd\(^{3+}\)). The host material has good optical, thermal, and mechanical properties and its structure favors a narrow fluorescent line width, yielding high laser gain and low operational threshold. The fundamental output wavelength from a Nd: YAG laser is 1.06414 μm, which is directly usable for some IR LIDAR applications. Its harmonics at 532, 355 and 266 nm are commonly used in UV/VIS LIDAR and in pumping devices such as dye lasers and OPOs.

A typical pulsed Nd: YAG laser oscillator\(^{(14)}\) uses cylindrical Nd: YAG rods with polished, antireflection (AR) coated end faces, enclosed in a water-cooled reflective flashlamp housing (e.g. with an elliptical reflector coupling the Nd: YAG rod to a linear xenon flashlamp at its respective foci). These flashlamp-pumped Nd: YAG rod modules are located in a laser cavity, often with mirrors chosen for unstable optical operation (to extract maximum power from the laser rod, and to tailor the laser beam to a diffraction-limited, quasi-Gaussian profile).\(^{(96)}\) The Nd: YAG laser cavity also usually incorporates a Q-switch (for regular pulsed operation) and optical elements such as waveplates and polarizers.
An amplifier stage, using further flashlamp-pumped Nd: YAG rod modules, is often added to boost the output power. Such Nd: YAG laser oscillator–amplifier systems are commercially available, with routinely available operating characteristics as follows: pulse repetition rate = 10 Hz, pulse duration = 5–10 ns, pulse energy = 1 J, and peak power ≥100 MW.

Nd: YAG lasers typically run on several longitudinal modes, yielding an optical bandwidth of ~1 cm⁻¹ and an uneven temporal profile owing to beating between those modes. Single longitudinal mode (SLM) operation of a pulsed Nd: YAG laser can be achieved by injection seeding with a narrowband 1.064-µm laser source (such as a single-mode diode laser or a miniature monolithic Nd: YAG laser). This yields a smooth temporal profile (free of mode-beating effects) and an optical bandwidth of ~50 MHz, close to the limit imposed by the Fourier transform of the pulse duration), in a high-quality, diffraction-limited laser beam. Injection-seeded Nd: YAG lasers have several advantages, all arising from SLM operation and compensating for its complexity: transform-limited optical bandwidth, smooth temporal profile and higher nonlinear-optical conversion efficiency.

The last decade has seen a dramatic growth in the availability, affordability and utility of laser-diode arrays as an alternative to flashlamp excitation of Nd: YAG and other pulsed solid-state lasers. All-solid-state laser systems pumped by laser-diode arrays offer higher overall efficiency relative to flashlamp-pumped systems, since the laser-diode emission can give a closer spectral match to the absorption band of a solid-state gain medium such as Nd: YAG. This in turn reduces the thermal load on the gain medium, yielding improved laser beam quality and much-increased pulse repetition frequency (e.g., diode-pumped Nd: YAG lasers can readily be run at ≥1 kHz, compared with ~10 Hz for typical flashlamp-pumped systems). The lower voltage requirements and compactness of diode laser pump power supplies provides a further significant advantage, especially for field-based applications such as LIDAR. The cost of laser-diode arrays is still relatively high (but decreasing steadily), although partially offset by their longer component lifetimes. Design parameters for all-solid-state Nd: YAG and other lasers are well defined and numerous systems are commercially available. They will certainly find widespread use in future LIDAR instruments, although their implementation may be slowed by the inertia of replacing flashlamp-pumped Nd: YAG lasers installed in existing mobile and airborne LIDAR facilities.

Nd: YAG lasers may be regarded as the industry standard against which other pulsed solid-state lasers are gauged. On the one hand, other materials can serve as alternative hosts for Nd³⁺, notably GSGG (gadolinium scandium aluminum garnet; Gd₃Sc₂Al₅O₁₁) doped with Nd³⁺ and Cr³⁺ gives Nd: Cr: GSGG lasers a better spectral match than Nd: YAG to flashlamp emission; glasses are used in very high-power Nd: glass laser amplifiers, although these are subject to poorer lasing thresholds, thermal properties, and optical distortion effects than Nd: YAG; YLF (yttrium lithium fluoride; YLiF₄) is transparent out to 1.5 µm, is less prone than Nd: YAG to thermal lensing and birefringence, and has higher energy storage capacity (owing to its lower gain). Mode-locked and Q-switched Nd: YLF laser oscillators (emitting with orthogonal polarizations at 1.053 and 1.047 µm) closely match the 1.054-µm wavelength of large phosphate glass Nd³⁺ laser amplifiers regularly used in fusion research. Diode-pumped Nd: YLF lasers have been used in IR LIDAR measurements of the atmospheric boundary layer, cirrus clouds, and volcanic aerosols.

Variation of transition metal ion as well as host material provides flexibility and diversity in pulsed solid-state lasers. This is particularly advantageous in extending IR LIDAR applications into the IR region beyond 1.06 µm. Pulsed IR lasers based on erbium ions (Er³⁺) are of considerable interest: Er: glass lasers emit at ~1.54 µm, in the eye-safe region used for optical telecommunications, and are crucial as fiber-optic amplifiers; Er: YAG lasers emit at ~2.94 µm, which coincides with the fundamental IR absorption band of water and is amenable to atmospheric sensing of H₂O by IR LIDAR. Pulsed IR lasers based on holmium (Ho³⁺) and thulium (Tm³⁺) ions in the 2-µm region: for instance, Tm: YAG and Tm: YLF emit at ~2.01 µm. Diode-pumped Tm: Ho: YAG and flashlamp-pumped Cr: Tm: Ho: YAG lasers yield output at ~2.08 µm and are useful for wind sensing. A CW 2.066-mm Ho: YLF laser has been developed recently for remote sensing of CO₂ and H₂O.

Many forms of “fixed-wavelength” laser can run at a variety of wavelengths other than that with maximum gain, by using wavelength-selective reflectors or intracavity elements. For instance, 1.065 µm is not the only possible emission wavelength of a Nd: YAG laser; others (in descending order of intensity at ~300 K) include 1.0615, 1.0738, 1.0646, 1.1121, 1.05205, 1.1159, 1.1127, 1.0780, and 1.3188 µm. The same is true of some gas lasers, such as the helium–neon (He–Ne) laser. The ubiquitous red He–Ne laser line at 632.8 nm is not in fact that with the highest gain. Many NIR He–Ne laser lines are accessible, notably those at 1.526 µm (the first gas laser emission line ever observed), 2.3951 µm, and 3.3913 µm.

Sensing with fixed-wavelength lasers makes the most of chance coincidences between discrete laser wavelengths and spectroscopic transitions in molecules of
interest. Fixed-wavelength lasers have the advantage of “auto-calibration” of detection wavelength and tend to be more robust, compact and/or easier to operate than line- or continuously tunable sources (such as dye lasers or OPOs). In one instance, an étalon-scanned Nd:YAG laser line at \( \sim 1.34 \mu m \) was used to monitor \( \text{CH}_4 \) via the P(4) feature in its \((v_2 + 2v_3)\) combination band. \(^{(103)}\)

Laser-spectroscopic monitoring of hydrogen fluoride (HF) gas in aluminum smelters has been performed by long-path absorption of IR He–Ne laser radiation at \( \sim 2.4 \mu m \). \(^{(104,105)}\) This HF sensor employs two He–Ne lasers: one operates at \( \lambda_{\text{on}} = 2.3958 \mu m \), coinciding with the R(5) fundamental absorption line of HF; the other is at \( \lambda_{\text{off}} = 2.3985 \mu m \), providing an interference-free reference. In proving trials, \(^{(105)}\) the two CW laser beams were transmitted along the ceiling of the potroom of an aluminum smelter to retro-reflectors at a range of up to 400 m. The He–Ne laser sensor is able to detect changes of airborne HF concentration as low as 0.01 mg m\(^{-3}\) (0.05 ppm) at a range of 270 m; its response time is routinely set at 15 s – much more rapid than conventional wet-chemical HF sensors. \(^{(106)}\) It is thereby feasible to monitor abrupt changes of HF emission inside the aluminum smelter potroom, arising from regular operations such as anode changing, crust breaking, and metal tapping.

### 4.2 Line-tunable Lasers

Several forms of molecular gas laser are line-tunable, able to operate on successive vibration–rotation emission transitions by simple cavity adjustments. The most notable are CO\(_2\) lasers, \(^{(18–21)}\) which operate in the wavelength range 9–11.5 \( \mu m \) with high wallplug efficiency (\( \sim 20\% \)) and have long been vital to atmospheric sensing by IR LIDAR.

A typical CW CO\(_2\) laser comprises a water-cooled tube with Brewster-angle IR-transparent windows, through which a low-pressure gas mixture of CO\(_2\), N\(_2\), and He flows, supporting a longitudinal glow discharge excited electrically. The tube is placed in an IR-resonant optical cavity with one or more wavelength-selective elements such as a Littrow-mounted diffraction grating, a prism, or an étalon; adjustment of this element allows successive laser lines to be selected. The emission spectrum of a regular CO\(_2\) laser comprises the P and R branches of two rotation–vibration bands of \(^{12}\)CO\(_2\), centered at 10.4 and 9.4 \( \mu m \), respectively; without wavelength selection, lasing is on the highest gain transition, 10.59-\( \mu m \) P(20).

The number of available CO\(_2\)-laser wavelengths can be increased markedly \(^{(21)}\) by operating on sequence bands (with an intracavity absorption cell to suppress regular laser lines and enhance hot-band emission). Isotopic modifications of CO\(_2\) such as \(^{13}\)CO\(_2\) or \(^{18}\)O\(_2\) can also be used in sealed laser discharge tubes (with Xe added to minimize dissociation of CO\(_2\)); the 9.1145-\( \mu m \) R(20) line of a C\(^{18}\)O\(_2\) laser is an agreed standard for atmospheric IR LIDAR \(^{(6,40,49)}\) since it has high gain and is far from absorption lines of natural-abundance CO\(_2\) in the air.

Not all CO\(_2\) lasers are CW. Most forms of IR LIDAR need CO\(_2\)-laser radiation that is emitted in pulses, rather than continuously. This can be attained by incorporating a Q-switch in the laser cavity \(^{(18,20)}\) or by atmospheric-pressure operation with a pulsed electrical power supply in the transversely excited (TE) mode. CO\(_2\) TE lasers can also be operated at higher pressures up to \( \sim 10 \) bar, where they become continuously tunable as a result of pressure broadening. \(^{(19)}\) Limited ranges of continuous tunability can also be obtained from waveguide CO\(_2\) lasers, which are typically excited by radiofrequency at atmospheric pressure and are relatively compact. \(^{(11,74)}\)

Many molecules have functional groups that cause their IR absorption spectra to fall within the wavelength range (9–11 \( \mu m \)) of line-tunable CO\(_2\) lasers. \(^{(52,107)}\) This makes CO\(_2\) lasers useful for many DIAL and long-path absorption applications, of which tropospheric ozone detection at \( \sim 9.6 \mu m \) has already been mentioned in section 1.5. \(^{(16)}\) In an early application of a continuously tunable CO\(_2\) waveguide laser operating in the vicinity of 9.5–9.6 \( \mu m \), Menzies studied the variation of atmospheric ozone line widths and absorption coefficients as a function of pressure and altitude. \(^{(74)}\) There are numerous examples of line-tunable CO\(_2\)-laser DIAL systems used to map atmospheric pollutants. \(^{(15,16,71)}\)

A recently reported IR DIAL technique \(^{(108)}\) employed CO\(_2\) lasers for quantitative multil wavelength detection of four gas-phase molecules that are of particular environmental interest: CH\(_3\)CCl\(_3\), C\(_2\)HCl\(_3\), CFC\(_2\)CF\(_2\)C\(_2\)Cl (Freon 113), and C\(_2\)H\(_4\). Their respective absorption characteristics at each of 40 CO\(_2\)-laser wavelengths were established in laboratory measurements with a 16-W CW CO\(_2\) laser; trailer-born, range-resolved field trials were then conducted with a pair of pulsed TE CO\(_2\) lasers to identify and quantify mixtures of the four gases in controlled releases at ranges of \( \geq 3 \) km, aided by chemometric data-analysis methods.

Another promising recent CO\(_2\)-laser application, known as BAGI (backscatter absorption gas imaging), \(^{(109)}\) uses a CW CO\(_2\) laser (typically 20 W, able to image gases at ranges up to 125 m) to produce rastered gas-plume images of IR absorption by backscattering from hard targets. The BAGI database covers \( \sim 80 \) detectable gases, most of them significant industrial pollutants. In a BAGI variant, a 3.3966-\( \mu m \) HE–NE laser is able to monitor methane. \(^{(109)}\)

Other recent papers \(^{(49,110–113)}\) demonstrate the ongoing utility of CO\(_2\) lasers for a variety of IR LIDAR applications. Such papers confirm that careful, systematic
calibration of various CO$_2$-laser LIDAR parameters, particularly backscatter coefficients from hard targets and aerosols, is less critical than in earlier work. For example, DIAL-type sensing by backscattering of two CO$_2$-laser wavelengths ($\lambda_{on}$ and $\lambda_{off}$) from atmospheric aerosols must incorporate variability with wavelength $\lambda_L$ of volume backscattering coefficients, $\beta(\lambda_L, R)$ in Equation (4). Corrections also need to be made for potential interferences from the many atmospheric species that absorb in the CO$_2$-laser region (9–11 $\mu$m). Lasers, to IR LIDAR applications, namely tunable solid-state pulsed, continuously tunable laser that are applicable lasers have no such limitation, but they generally require some form of active wavelength control. In this regard, the spectroscopic coincidence of interest. Continuously tunable lasers have no such limitation, but they generally require some form of active wavelength control and calibration. This section reviews several forms of focused, continuously tunable laser that are applicable to IR LIDAR applications, namely tunable solid-state lasers, notably titanium–sapphire (Ti$^{3+}$: Al$_2$O$_3$) and alexandrite (Cr$^{3+}$: BeAl$_2$O$_4$), TDLs, and semiconductors TDL sources.

Some optically pumped solid-state lasers are confined to one or more discrete wavelengths (as treated in sections 4.1 and 4.2), but others have spectrally broad gain profiles and can be operated as continuously tunable coherent sources via wavelength-selective intracavity elements or injection seeding. One such device is the titanium–sapphire laser (Ti$^{3+}$: Al$_2$O$_3$), which operates over the wavelength range 0.7–1.05 $\mu$m, either CW (pumped by an argon-ion laser) or pulsed (pumped by an Nd: YAG or Nd: YLF laser). Such a laser has been used in a multiwavelength LIDAR system to measure aerosol size distributions. A double-pulsed TDL-seeded Ti$^{3+}$: Al$_2$O$_3$ laser operating around 820 nm has been incorporated in airborne water-vapor IR DIAL systems used in the context of project LASE and its predecessors.

Alexandrite lasers are also important solid-state sources for airborne water-vapor NIR DIAL measurements. Alexandrite, a flashlamp-pumped laser material in which Cr$^{3+}$ ions are doped in a chrysoberyl (BeAl$_2$O$_4$) lattice, avoids some of the “three-level-laser” difficulties of ruby. Its room-temperature tuning range is 700–820 nm. Commercially available alexandrite lasers typically deliver Q-switched output pulses of $\geq$100 mJ, continuously tunable (by means of intracavity étalons and birefringent or Lyot filters) in sweeps of $\sim$150 cm$^{-1}$, with optical bandwidths of $\sim$1 cm$^{-1}$.

Injection seeding by a narrowband laser (e.g. a CW TDL or another narrowband, low-power laser) provides a useful wavelength-control strategy for either pulsed Ti$^{3+}$: Al$_2$O$_3$, or alexandrite lasers. Relevant applications of such lasers are aimed at IR DIAL sensing of humidity via the third-overtone ($\nu_3$OH = $\sim$730 and $\sim$820 nm) and second-overtone ($\nu_2$OH = $\sim$940 nm) absorption bands of H$_2$O vapor and of gas density and temperature via the 760-nm magnetic-dipole vibronic band of O$_2$.

For reliable IR DIAL measurements such as these, spectral purity (i.e. the narrowband proportion of laser output energy) needs to be as high as possible. And has been optimized to at least 99.9% in the various injection-seeded Ti$^{3+}$: Al$_2$O$_3$ and alexandrite lasers used. Such lasers, when used in the “$\lambda_{on}$” mode of IR DIAL, also generally need some form of active wavelength stabilization and locking to the exact peak of the spectroscopic feature of interest.

Ground-based IR LIDAR has been used recently to detect LIF from potassium atoms in meteor trails blown by winds into the path of vertically directed 769.9-nm radiation (resonant with the D$_2$ fine-structure line of K) from a tunable TDL-seeded alexandrite laser. Other recent developments include a tunable, narrowband, CW 2.066-µm Ho : YLF laser, injection-seeded by a Ti$^{3+}$: Al$_2$O$_3$ laser; this has been evaluated for remote sensing of atmospheric CO$_2$ and H$_2$O.

Tunable dye lasers use optically pumped fluorescent organic dyes in solution and are vital to many forms of laser spectroscopy. Continuous narrowband tunability is achieved by resonating the fluorescent emission in an optical cavity incorporating a diffraction grating and/or étalon). Pulsed dye lasers, pumped by flashlamps or another laser, are useful for UV and visible LIDAR applications, particularly laboratory trials when the handling of dyes and flammable solvents can be tolerated. However, their direct utility as pulsed, coherent sources for IR LIDAR applications is less evident. NIR dyes extend to $\sim$0.95 $\mu$m, but solid-state lasers such as
Examples of such TDL DFG methods include long-path absorption studies of atmospheric pollutants such as SO2 (145) and formaldehyde (H2CO) (146) (see section 4.4 for details).

4.4 Nonlinear-optical Coherent Infrared Sources

Nonlinear optics (36–38, 56, 100) involves the interaction of a number (σ > 2) of optical waves in a medium with a nonlinear-optical susceptibility tensor χ(2–4). These waves (each with a frequency ν1, ν2, . . . , νσ) obey two conservation conditions, one for energy [Equation (13)]:

\[ ν_1 + ν_2 + \cdots + ν_σ = 0 \]  

and the other (expressed in terms of wave vectors \( k_i \)) with \( j = 1, 2, \ldots, σ \) with magnitudes \( k_i = 2πν_i/c = 2πν_i/λ_i \), where \( n_i \) is the refractive index at vacuum wavelength \( λ_i \) and \( c \) is the speed of light) for momentum [Equation (14)]:

\[ k_1 + k_2 + \cdots + k_σ + Δk = 0 \]  

where \( Δk \) is a phase-mismatch increment that must be minimized to optimise the efficiency of the nonlinear-optical process of interest. Each frequency component has a positive or negative sign associated with phase relationships. We now consider three nonlinear-optical processes that can generate coherent IR radiation suitable for atmospheric sensing.

One such nonlinear-optical process is stimulated Raman scattering (SRS), the first-Stokes version of which is useful as a passive (i.e. adjustment-free) means of converting high-power pulsed laser radiation at frequency ν1 to a lower IR frequency νR determined by the Raman shift \( Δν_R \), as in Equation (2), of a suitable Raman-active medium. First-Stokes SRS from isotropic fluids is a coherent four-wave process (σ = 4) with \( |ν_{12}| = |ν_{23}| = ν_{1L} \), and \( |ν_{34}| = ν_R \) which is nonparametric and automatically phase-matched (\( Δk = 0 \)) in the forward-scattered direction. Commonly used Raman-shifting media are high-pressure gases such as H2 (\( Δν_H/c = 4155 \text{ cm}^{-1} \)), D2 (2987 cm−1), and CH4 (2917 cm−1). For instance, pulsed Nd:YAG laser radiation (1.064 μm) can be Raman-shifted in high-pressure CH4 to an eye-safe wavelength (1.543 μm); this approach has proved convenient in a number of IR LIDAR instruments. (80, 90) Likewise, SRS is a way to generate longer wavelength tunable radiation for spectroscopic sensing of the atmosphere, by downconverting continuously tunable sources such as dye lasers. (147) The tuning range (0.70–0.82 μm) of an alexandrite laser can be extended by first-Stokes SRS in H2, D2, and CH4 to cover most of the range 0.9–1.2 μm (101, 111) (and beyond, using higher order Stokes and anti-Stokes processes (34–37)).
Another form of nonlinear-optical wavelength conversion involves coherent three-wave processes \((\sigma = 3)\) in noncentrosymmetric solid-state media\(^{(100)}\), including the second-harmonic \((v_3 = 2|v_1|)\) and sum-frequency \((v_3 = |v_1 + v_2|)\) generation processes widely used to upconvert pulsed laser radiation. In the IR LIDAR context, two such processes are important. One case is coherent DFG, with two input laser frequencies \(|v_1| = v_L\) and \(|v_2| = v'_L\) \((<v_L)\), an IR output frequency \(v_IR = [(v_L - v'_L)]\), and a phase mismatch \(\Delta k = [k_IR - k_L + k'_L]\). The other is that associated with an OPO or optical parametric amplifier (OPA).\(^{(22,148–154)}\) In this case, a single laser input wave \(\text{“pump”},\) frequency \(v_P\) and two coherent output waves \(\text{“signal”},\) frequency \(v_S;\) \text{“idler”}, frequency \(v_I;\) \(v_S \geq v_I\) obey both energy conservation \((v_P = v_S + v_I)\) and phase-matching \((k_P - k_S - k_I - \Delta k = 0)\) conditions, as in Equations (13) and (14).

The close complementarity between DFG and an OPO should be noted.\(^{(151)}\) In fact, the cases of intracavity DFG and injection-seeded OPOs \((v_{\text{seed}} = v_S \text{ or } v_I)\) are distinguished only by the relative amplitudes \(A\) of the waves at \(v_L\) and \(v'_L\) \((A_L\text{ typically comparable to } A'_L)\) in the former case and those at \(v_P\) and \(v_{\text{seed}}\) \((A_P \gg A_{\text{seed}})\) in the latter.

In both DFG and OPOs, phase matching is needed to minimise \(\Delta k = |\Delta k|\). Traditionally, this is done by adjusting the angle and/or temperature of a birefringent nonlinear-optical crystal via its ordinary- and extraordinary-ray refractive indices.\(^{(100)}\) A more recent alternative is to use quasi-phase-matched (QPM) media tailored for specific wavelength sets by periodic structuring; periodically poled lithium niobate (PPLN) is a prominent example.\(^{(155)}\)

DFG in bulk media such as lithium niobate \((\text{LiNbO}_3)\) has long been a dependable source of narrowband, high-quality tunable IR radiation, as illustrated by CW IR spectroscopic studies of \(\text{CH}_4\) and other molecules by Pine.\(^{(156)}\) Recent progress has been made in developing compact tunable CW mid-IR sources based on DFG in birefringently phase-matched media such as \(\text{AgGaSe}_2\) (generating 8.7-\(\mu\)m radiation as the difference of 1.554 and 1.319\(\mu\)m, for sensing of \(\text{SO}_2\))\(^{(145)}\) and in QPM media such as PPLN \((\text{by DFG mixing of TDLs in the} 0.8-1.6\mu\text{m range, yielding} 3.5-\mu\text{m radiation to monitor trace gases such as} \text{H}_2\text{O, H}_2\text{CO, and CH}_4\).\(^{(145,146,157,158)}\) Such advances combine the wavelength-extension advantage of nonlinear optics with photonics technology \((\text{e.g. TDLs, optical fibers, and fiber amplifiers}); \text{they have contributed to NASA’s Lunar–Mars Life Support Test program.}^{(146)}\)

Relative to DFG, OPOs offer the prospect of high output power and coherence, both of which are advantageous for remote sensing of the atmosphere. Of the many possible varieties of OPO, we concentrate discussion on those with 2–10-ns pulse duration, which is compatible with the range-resolution requirements of many IR LIDAR and DIAL applications.

A simple pulsed OPO uses a suitable nonlinear-optical crystal \((\text{either birefringently phase-matched or QPM})\) in a two-mirror optical cavity that is resonant at either \(\lambda_S\) or \(\lambda_I\). It is pumped at \(\lambda_P\) by a pulsed monochromatic coherent source \((\text{e.g. harmonics of an Nd: YAG laser}); \text{Such a free-running OPO (with no wavelength-selective elements)}\) has a broad optical bandwidth \(\sim 10\text{ cm}^{-1}\) or more, depending on several factors: the refractivity, dispersion, and absorption of the OPO medium; the wavelengths \(\lambda_S, \lambda_I, \text{ and } \lambda_P;\) the type of phase matching; the crystal dimensions; the cavity reflectivity and effective number of passes of the resonated wave; and the bandwidth, divergence, pulse duration and pulse energy of the pump radiation.

Narrowband operation of a pulsed OPO can be achieved by means of wavelength-selective elements, such as intracavity gratings and étalons. This was realised before 1980 by Byer and colleagues,\(^{(22,149–151,159)}\) whose pulsed \(\text{LiNbO}_3\) OPOs provided a practical narrowband pulsed spectroscopic source, continuously tunable under computer control over wide IR ranges with an optical bandwidth of \(\sim 0.1\text{ cm}^{-1}\). This form of tunable OPO system was successfully applied in a number of atmospheric remote-sensing demonstrations, applied to CO \((2.3\mu\text{m} \text{ and a range of} >100\text{ m});\(^{(160)}\) \(\text{SO}_2\) \((4.0\mu\text{m} \text{ and 120-m range});\(^{(161,162)}\) \(\text{CH}_4\) \((1.66\mu\text{m} \text{ and over a} 2.7-\text{km column});\(^{(162)}\) \text{and} \text{H}_2\text{O} \((\text{around} 1.75\mu\text{m}, \text{both for a} 2\text{-km atmospheric column});\(^{(163)}\) and range-resolved up to \(\sim 1\text{ km}^{(164)}\).\)

After that early \((\text{pre-1982})\) progress on pulsed OPOs, relatively few OPO-based advances in IR LIDAR appear to have been made during the next 15 years. This is probably because such tunable pulsed OPOs proved difficult to operate and damage prone \((\text{largely because intracavity losses from gratings and étalons caused the operating threshold to approach the damage threshold of materials such as LiNbO}_3).\) A revival in OPO technology in the last decade\(^{(22,152–154)}\) is attributable to new nonlinear-optical materials\(^{(100)}\) such as \(\text{BBO} (\beta\text{-barium borate})\) and \(\text{KTP} (\text{potassium titanyl phosphate}), \text{combined with high-performance pump lasers}^{(14,97,98)}\) and advanced IR OPO system designs.\(^{(165)}\) OPOs now appear to have regained acceptance as high-power pulsed tunable sources suitable for IR LIDAR applications.

One particularly successful approach to controlling the wavelengths and optical bandwidth of a pulsed OPO tuning is injection seeding\(^{(22,152,154,166–173)}\) with narrowband, tunable radiation from a low-power, narrowband external source. This simplifies OPO construction, by separating its wavelength-control function from that of power amplification.
A TDL-seeded LiNbO$_3$ OPO has been used by Milton et al.\cite{109} to demonstrate range-resolved 3.4-µm IR DIAL measurements of atmospheric CH$_4$ at ranges up to 0.5 km. Single-mode TDLs have been exploited in the author’s laboratory for continuously tunable injection seeding of pulsed IR OPOs of LiNbO$_3$ in both its bulk\cite{170} and QPM PPLN\cite{171,172} forms; optical bandwidths are as low as $\sim$0.005 cm$^{-1}$, approaching the Fourier-transform limit of the pulsed radiation.\cite{109} Their performance has been verified by recording OPO-scanned spectra of CH$_4$, both as a gas (Doppler-broadened) and in a supersonic free jet (sub-Doppler).

Another significant TDL-seeded OPO system designed for airborne water-vapor IR DIAL measurements is that of Ehret et al.\cite{173,174} It comprises a BBO or KTP ring-cavity OPO pumped at 532 nm and TDL-seeded at its 942-nm signal wavelength. This system is able to monitor the second-overtone absorption band (3$\nu_{\text{OH}}$) of H$_2$O, which offers higher sensitivity than the third-overtone band (4$\nu_{\text{OH}}$) region at $\sim$725 nm accessed in earlier airborne dye-laser-based IR DIAL studies by the same group.\cite{135}

Finally, we note an intrinsic advantage for IR-spectroscopic sensing that is shared by both DFG and OPOs, namely coherent downconversion of available pump-laser radiation to longer wavelengths.\cite{151} It is now relatively routine to be able to tune OPOs throughout the NIR region to beyond 4 µm. Even longer OPO output wavelengths [as far out as 12 µm\cite{22}] can be accessed by using lasers with wavelengths longer than 1.064 µm [e.g. $\sim$2 µm\cite{14} to pump OPO gain media such as ZnGeP$_2$, AgGaS$_2$, or AgGaSe$_2$.\cite{100}

### 4.5 Multiwavelength Coherent Sources for Differential Absorption LIDAR and Mutiplex Sensing

An essential requirement for atmospheric sensing based on differential long-path laser absorption\cite{57,58} or (range-resolved) DIAL\cite{15,16,70,71} is a coherent light source capable of generating two specific wavelengths, $\lambda_{\text{on}}$ and $\lambda_{\text{off}}$. These are effectively the “signal” (resonant with the molecule of interest) and “reference” (nonresonant background) wavelengths for differential detection, as explained in section 2.2. There are several ways to implement such dual-wavelength laser-based sensing techniques:

1. **Separate lasers** – two discrete lasers with their output beams combined and aligned to copropagate to the remote target regions;

2. **Sequential multiwavelength operation** – a single tunable laser that can be sequentially scanned or switched between $\lambda_{\text{off}}$ and $\lambda_{\text{on}}$, preferably in a time interval [typically $\leq$1 ms\cite{16}] that is short compared with appreciable atmospheric turbulence;

3. **Simultaneous multiwavelength operation** – a single laser with a broad spectral gain profile from which the two wavelengths $\lambda_{\text{on}}$ and $\lambda_{\text{off}}$ can simultaneously be extracted (e.g. by a doubly resonant optical cavity or by injection seeding).

A simple example of strategy 1 is the 2.4-µm He–Ne laser long-path absorption sensor for HF emissions in aluminum smelters\cite{104–106} as recorded in section 4.1. Likewise, an early implementation of water-vapor IR DIAL used 724-nm dye-laser radiation for $\lambda_{\text{on}}$ and a portion of the 649-nm ruby-laser pump radiation for $\lambda_{\text{off}}$. Concerning strategy 2, various schemes\cite{146} enable a CO$_2$ laser to be scanned rapidly from one wavelength to another; these usually entail a rotatable intracavity mirror or diffraction grating and can be run either quasi-CW or pulsed (at rates $>$100 Hz). Various schemes of type 3 enable a dye laser to operate simultaneously on two output wavelengths; these entail splitting the cavity into two paths that are separately tunable (e.g. by insertion of an adjustable wedge plate or by using two separate diffraction gratings)\cite{71,175} or by using adjacent modes of an intracavity étalon.\cite{135} Injection-seeded Nd: YAG lasers are simultaneously operable on two output wavelengths\cite{176–178} separated by a multiple of the free spectral range (FSR) of the laser cavity.

The above-mentioned FSR-interval restriction has been relaxed in a flashlamp-pumped 800-nm Ti$^{3+}$ : Al$_2$O$_3$ laser\cite{128} by sustaining high-order transverse modes in the laser cavity and injection-seeding with a single TDL whose wavelength was current-tuned from one laser shot to the next; broadband background limited the device’s utility for H$_2$O-vapor IR DIAL but it was useful frequency doubled for DIAL detection of NO$_2$ at $\sim$400 nm.\cite{138}

Strategy 1 has been adopted by NASA for early airborne IR DIAL sensing of H$_2$O vapor, with $\lambda_{\text{on}}$ and $\lambda_{\text{off}}$ in the 730-nm region generated respectively by a tunable alexandrite laser and a Nd : YAG-pumped dye laser;\cite{16,77,125} these were fired sequentially with a temporal separation of $\sim$0.3 ms, allowing a common detector and transient digitizer to be time shared. Similar time sharing was adopted in NASA’s subsequent LASE project;\cite{16,81–83,87,127} where an airborne H$_2$O-vapor IR DIAL system used method 2 with a double-pulsed 820-nm Ti$^{3+}$ : Al$_2$O$_3$ laser injection-seeded by two separate TDL wavelengths (controlled by rapidly varying the current $i$ applied sequentially to a single diode). Strategy 2 is also employed in a narrowband IR DIAL system designed for atmospheric water-vapor and temperature profiling,\cite{78,79,130,132} using an intracavity electro-optic switch in the CW single-mode Ti$^{3+}$ : Al$_2$O$_3$ “master” laser that seeds the Q-switched alexandrite “slave” laser.
to generate a double-pulsed sequence of two output wavelengths ($\lambda_{\text{on}}$ and $\lambda_{\text{off}}$); these are typically separated by a frequency of 50 GHz (1.7 cm$^{-1}$) and a delay interval of 10 ms.\(^{132}\)

A novel three-wavelength technique has been adopted in the most recent phase of NASA’s project LASE,\(^{81}\) with alternate shots of the TDL-seeded, double-pulsed Ti$^{3+}$:Al$_2$O$_3$ laser operated on pulse pairs ($\lambda_{\text{on}}, \lambda_{\text{off}}$) and ($\lambda_{\text{side}}, \lambda_{\text{off}}$), where $\lambda_{\text{side}}$ is accurately positioned on the slope of a strong absorption feature of H$_2$O vapor. This approach permits almost simultaneous airborne measurements of atmospheric water vapor at high altitude (up to 14 km) and at lower altitudes (down to sea level), along a single ground track.

Injection-seeded OPOs provide another convenient form of dual-wavelength coherent source suitable for spectroscopic remote sensing. Sequential strategy 2 has been used in recent OPO-based IR DIAL demonstrations,\(^{169,174}\) either switching the TDL-seeded OPO output between $\lambda_{\text{on}}$ and $\lambda_{\text{off}}$ (both narrowband) on alternate shots of the pump laser\(^{169}\) or switching between narrowband, TDL-seeded ($\lambda_{\text{on}}$) or broadband, unseeded ($\lambda_{\text{off}}$) operation.\(^{174}\)

Injection seeding also enables OPOs to be used as a simultaneous, dual-wavelength coherent source for spectroscopic remote sensing. This has been verified in the author’s laboratory.\(^{179,180}\) Our approach\(^{22,166,170,179,180}\) avoids the limitations of cavity FSR effects by passive control of an OPO cavity with one of its reflectors slightly misaligned (by $\sim$2 mrad). Continuous tuning of the injection-seeded OPO signal and idler outputs is then facilitated by decreasing the effective finesse of the OPO cavity, thereby avoiding mode hops as the TDL seed wavelength is scanned (without needing to lock the OPO cavity length to the TDL wavelength). Two separate TDLs can then be used to injection seed such a misaligned OPO cavity and simultaneously generate spectroscopically tailored dual-wavelength signal and idler outputs that are not restricted by OPO-cavity FSR.\(^{179}\) However, backconversion sideband effects arise when the OPO is run much above its operating threshold.\(^{180}\)

This dual-wavelength spectroscopic tailoring concept is capable of extension to multiwavelength remote sensing applications. This would require a source of coherent, pulsed radiation to generate simultaneously a structured set of discrete wavelengths, each of which is set to be on- or off-resonance with characteristic features in spectra of molecular target species of interest. Such remote sensing could be by DIAL or long-path absorption. Figure 2 portrays a multiplex system of this type that is under development in the author’s laboratory. It uses a set of single-mode DBR TDLs and a fiber-optic switch (all computer-controllable) to injection seed a multiwavelength passive-cavity OPO. Appropriate modulation and

Figure 2 Conceptual schematic of a spectroscopically tailored multiwavelength IR DIAL system.
demodulation sequences can then decode the resulting spectroscopic signals, with a multiplex advantage for sensitivity and specificity. Beyond this preliminary proof of principle based on discrete DBRs as injection seeders, the ultimate multiplex spectroscopic tailoring capability could be by computer-addressable monolithic devices such as two-dimensional rastered multiwavelength VCSEL arrays.\(^{181,182}\) The potential of multiple-wavelength diode arrays has also been noted by NASA\(^{183}\) as a means of automated, sequential atmospheric sensing.

### 5 PERSPECTIVES AND FUTURE DEVELOPMENTS

LIDAR measurements in the IR region (including long-path IR laser absorption, according to this classification) cannot meet all of our atmospheric monitoring requirements and should not be set apart from what can be determined by other optical techniques: both UV/VIS LIDAR\(^{3–6}\) and “laser-free” techniques such as DOAS, FTIR, and gas-filter correlation methods.\(^{184}\) IR LIDAR, on which we have necessarily focused, is not always the preferred or sole optical technique needed in a given atmospheric monitoring application. For instance, in atmospheric sensing that characterises molecular species by their IR spectra, FTIR spectroscopy (e.g. long-path absorption with broadband light)\(^{185}\) yields minimum detection limits in the parts per billion range\(^{59,184}\) — generally more sensitive than IR DIAL or long-path IR laser absorption. IR LIDAR techniques come into their own, relative to FTIR, when range-resolved or highly specific molecular information is sought over very long optical paths (>0.5 km).

Another relevant comparison can be made between range-resolved IR DIAL and Raman LIDAR, particularly in the context of monitoring of atmospheric water vapor. Both techniques are based on molecular vibrational spectra,\(^{52}\) but Raman LIDAR\(^{53–55}\) requires only a fixed-wavelength laser in contrast to the more elaborate tunable or multiwavelength sources needed for IR DIAL (as surveyed in section 4). Some of the traditional drawbacks of Raman LIDAR\(^{24,33,34,78}\) are its relatively low scattering cross-section (which necessitates high UV or visible laser power and large telescope area), its limited applicability in daylight conditions (owing to signal contamination by background radiation), possible interferences from fluorescing media, and its lack of inbuilt absolute calibration. Many of these limitations appear to have been minimized in recent water-vapor Raman LIDAR developments,\(^{186}\) using 355-nm pulsed laser excitation and high-rejection optical bandpass filters for simultaneous short- and long-range LIDAR sensing of aerosols (by elastic Mie scattering), H\(_2\)O vapor (\(\Delta v_R \approx 3652\) cm\(^{-1}\)), and N\(_2\) (\(\Delta v_R \approx 2331\) cm\(^{-1}\), for real-time ratiometric calibration) in a transportable unit capable of unattended day- and night-time operation. A critical comparison\(^{78}\) of IR DIAL and Raman LIDAR, in the context of atmospheric water-vapor profiling, concludes that the two techniques are complementary for ground-based sensing (but that Raman LIDAR from air- or spaceborne platforms is unrealistic) and that there is little to separate their performance in tropospheric monitoring applications.

Subtle choices are also sometimes needed between different modes of IR LIDAR detection, for instance, whether to employ heterodyne detection or not,\(^{187}\) or trade-offs between using shorter-wavelength IR lasers (which are easier to use, more readily available, or of higher performance than those at longer wavelengths) and correspondingly weaker absorption cross-sections of IR overtone- or combination-band spectra relative to longer-wavelength IR fundamental bands.

The distinctive utility of IR LIDAR techniques can be attributed to three key features:

1. The higher efficiency of scattering of IR radiation from aerosols (relative to that from molecules, which are favored at shorter wavelengths) enables vital meteorological and environmental measurements on clouds, winds and particulates\(^{6,40,49}\) and yields the “distributed mirror” advantage\(^{68}\) that is used in range-resolved IR DIAL.\(^{15,16,70,71}\)

2. The molecular information content of IR absorption spectra\(^{52,57–59}\) provides characteristic signatures for many significant atmospheric species including H\(_2\)O, CO\(_2\), CO, NO, NO\(_2\), O\(_2\), CH\(_4\), H\(_2\)CO and myriad other organic molecules, SO\(_2\), and even O\(_2\) (via its NIR magnetic-dipole bands\(^{143}\) – but not its diatomic partner in the air, N\(_2\)).

3. The versatility of coherent tunable IR sources (lasers, OPOs, and other nonlinear-optical devices) is well suited to DIAL and long-path laser absorption measurements.

Aspect 1 has been adequately discussed in sections 1 and 2. With regard to aspect 2, it should be noted that the complex mixtures of molecules in the air can often lead to severe interference effects when IR spectra are employed for analysis purposes. FTIR, with its broadband advantage, can then be helpful in providing survey spectra to identify a set of characteristic wavelengths suitable for multiwavelength IR LIDAR measurements. Recent IR LIDAR work has been making increasing use of chemometric techniques, such as multiple linear regression\(^{108}\) or principal component analysis\(^{188}\) to address this type of problem.
Aspect 3 provides the dominant theme of this article. As in the past, we can expect further advances in IR LIDAR technology to rely heavily on new laser, nonlinear-optical, and photonics technology. One instance of this is the spectroscopically tailored multiwavelength OPO source proposed in the context of Figure 2, with its blend of such technologies (DBR TDLs, fiber-optic switches, VCSEL arrays, multiplex OPO injection seeding, etc.) involved.

Further development (and improved availability) of solid-state IR photodetector technology\(^{75,76}\) is needed for LIDAR to take full advantage of the current state of the art in tunable IR lasers, OPOs, OPAs, and DFG devices. Silicon APDs have already been accepted in NIR LIDAR applications\(^{77,88}\) and their Hg(Cd, Mn)Te counterpart\(^{76}\) is an enticing prospect for mid-IR remote sensing. The same sense of anticipation applies to array detectors, such as HgCdTe CCDs\(^{75,76}\) with their potential for mid-IR imaging and multiplex spectroscopy, as has recently been demonstrated in the context of broadband UV/VIS DIAL.\(^{189}\)

Whatever the future prospects of remote sensing of the atmosphere,\(^{190}\) it seems certain that spaceborne LIDAR systems will play an increasingly significant role, with satellite-based mapping of water vapor, ozone, clouds, aerosols, and meteorological conditions in the Earth’s atmosphere among their top priorities. LIDAR-in-space systems\(^{40,146,191}\) in turn pose formidable technological challenges in terms of compactness, ruggedness, sensitivity, automation, and long-term reliability. This is an obvious new frontier for IR LIDAR. However, it should be recognized that spaceborne LIDAR projects,\(^{82,83,88}\) either realized (e.g., LITE) or immediately projected (e.g., PICASSO/CENA), are so far confined to fixed-wavelength ‘‘nonresonant’’ studies of aerosol backscattering. Payload restrictions and technological complexities appear to cause spaceborne IR DIAL systems (using a tunable or multiwavelength laser for spectroscopic applications such as global sensing of atmospheric water vapor) to be held at a feasibility study stage.\(^{82,87,191}\)

### ACKNOWLEDGMENTS

Research funding from the Australian Research Council is gratefully acknowledged. Thanks are due to Charles Halloway, Dr Yabai He, Maria Hyland, and Richard Shorten for valuable assistance. It is also appropriate to pay tribute to the many authors who have built up the formidable body of literature on laser-based atmospheric sensing, particularly that cited in section 1.2; they have helped to make this author’s task both a pleasure and a revelation.

1 Introduction

Introduction

A large number of molecules of interest in air monitoring are accessible to IR spectroscopy, such as O₃, N₂O, NO, NO₂, HONO, HNO₃, CO, CO₂, H₂O₂, HCHO, HF, SiF₆, CF₂Cl₂, H₂S, and OCS. All of these trace constituents of the atmosphere have been detected and their concentrations measured by laser spectroscopy. Detection levels to below 100 ppt are reported with temporal resolution of the order of minutes. Thus, tunable mid-IR diode laser spectroscopy is clearly a universal monitoring technique.

The concentrations of single components are of interest when monitoring air quality by representative species. However, the detection of a number of compounds is important for an understanding of atmospheric chemical reactions. At present many details of the processes that govern the natural destruction of man-made pollutants and the resultant formation of new compounds are unknown. In the longer term, it will be necessary to monitor a list of compounds in order to keep track of the development of the atmosphere's composition, to ensure that it does not change too rapidly.

This article describes tunable mid-IR diode laser spectroscopy in terms of three specific systems. The first has been used for air monitoring on board aircraft. This system can be regarded as typical of laboratory systems but shows that such systems are rugged and can be used for mobile campaigns.

The second example was developed for the special purpose of atmospheric measurement during a rocket mission. This system can be regarded as typical of laboratory systems but shows that such systems are rugged and can be used for mobile campaigns.

The second example was developed for the special purpose of atmospheric measurement during a rocket mission. This system was designed to demonstrate the ability of the mid-IR diode laser technique to withstand the demanding conditions of a rocket flight.

Infrared (IR) spectroscopy is a proven tool for gas analysis, and tunable mid-IR diode laser absorption spectroscopy is a special technique giving optimum sensitivity, selectivity and measurement speed for most molecules of interest. Molecules such as the NOₓ family (N₂O, NO, NO₂, HONO, and HNO₃) can be detected selectively down to well below part per billion levels. The technique works well with all molecules having line spectra and thus is quite universal. It is conceptually simple and detects gases by repetitively scanning absorption lines, which is possible due to the narrow laser line width and easy laser tuning. The scanning procedures of diode laser spectroscopy optimally reduce background fluctuations. Basic operation principles are explained in the article.

Alternative techniques are well established and often allow detection of single components at lower system cost, but in general need specific sample pretreatment that makes the results often difficult to compare. Mass spectroscopy is an alternative multicomponent technique that reaches comparable selectivity, but only with preselection processes which induce calibration problems of their own, such as matrix-dependent sensitivity. In order to give an insight into the capabilities of tunable mid-IR diode laser absorption spectroscopy, three exemplary systems are treated in detail for air monitoring from airplanes, from rockets, and gas analysis of combustion exhaust. System parameters are explained, and system performance is compared with alternative techniques.
The last example comes from emissions monitoring in industrial environments. This differs from the other two in that the air samples may be at temperatures up to several hundred degrees centigrade and can be contaminated with material such as soot, that make analysis difficult. Tunable mid-IR diode laser spectroscopy can cope with such samples, in many cases even without filtering. Additionally, this system demonstrates the capabilities of a diode laser gas analyzer designed to be operated by non-specialist personnel. Most air monitoring systems with really superior performance (such as the first two examples) are routinely operated by well trained scientific personnel.

These examples cover all possible questions as to the practical applicability of the technique, showing it also to be sensitive, selective, and fast. At present, however, tunable diode laser gas analyzers for high performance air monitoring are custom made, custom adopted, or even home-built, which makes them expensive and needing specialist operators. Tunable mid-IR diode laser spectroscopy is therefore used mostly for tasks that other techniques fail to resolve.

The following section introduces the basic technical and scientific features of these instruments, and compares them with other, competing techniques.

2 TUNABLE DIODE LASER ABSORPTION SPECTROSCOPY BASICS

In essence, tunable diode laser absorption spectroscopy (TDLAS) is just another spectroscopic technique for gas analysis. However, whereas conventional IR spectroscopy uses a thermal radiation source combined with a spectroscopic filter (such as an interference filter, a monochromator, or a Fourier transform spectrometer), the diode laser radiation source is itself tunable. This achieves gains in spectral resolution, spectral power, and speed and ease of tuning. Also, very good local resolution is obtained which is diffraction limited, thereby offering the potential of a superior long optical path. One loses wide access to spectral data due to the comparably small total spectral width available from a single laser. Use of laser radiation leads to unwanted interferences due to the high optical quality of the beam, which may get annoying in some applications, and one pays for the gained laser advantages by the fact that present prices (1999) of systems are high.

The main factor affecting cost is that of mass production. Single diode lasers of good stability cost between $\leq$2000 and $\leq$4000, if made in quantities of less than a few hundred per year. Typical spectroscopic applications of TDLAS require spectral resolution of the radiation. The laser drive current also has to be extremely stable and the laser temperature stable to some millikelvin in order to achieve laser stability to $10^{-5}$ of the wavelength. Although such requirements can be met by dedicated laboratory electronics, and might well be attained in mass production, the price of the corresponding electronic equipment is of the order of some tens of $\leq$1000.

Systems for atmospheric analysis with TDLAS are today made in small quantities or single units, and the production costs (often including special requirements) range from some $\leq$50 thousand to $\leq$1 million. At present mass production cannot be expected, but the market is slowly growing.

Returning to technical and scientific topics, good spectral resolution is one of the keys to laser spectroscopy success. IR gas spectra of the smaller molecules are composed of many lines. These lines are broadened by molecular movement relative to the radiation propagation. The corresponding Doppler line width depends on temperature (molecular motion increases with thermal energy) and on the molecular mass (smaller molecules with the same energy travel faster). At room temperature, typical Doppler line widths are of the order of several $10^{-6}$ of the peak wavelength. A wavelength of $\lambda = 10\,\mu m$ corresponds to a wavenumber $\nu = 1/\lambda = 1000\, cm^{-1}$. The lines are further widened by collisions between molecules. At atmospheric pressure this width is several $10^{-4}$ of the peak wavenumber. This width is proportional to pressure, and at atmospheric pressure frequently leads to the overlap of neighboring lines, so that spectral bands are formed rather than isolated lines. Also, lines from different gas species present may overlap. Therefore, selectivity of spectroscopic analysis is hindered by line width.

An example of molecular line structure is shown in Figure 1. The lines shown are calculated numerically, and correspond precisely to experimental observations. The line width of this light molecule (HCl) is much narrower than the line separation, hence even a medium resolution spectrometer would be able to resolve these lines. The main lines are found close to $\nu = 3\,\mu m$ or $\nu = 3000\, cm^{-1}$ (3333 1/2 cm$^{-1}$, to be exact). Higher harmonics of these are observed at a half and a quarter of the wavelength and can also be used for atmospheric analysis, albeit at a sensitivity reduced by roughly two orders of magnitude per harmonic step. This observation can be generalized – most molecules of interest absorb strongly and specifically somewhere in the wavelength range 3–15µm (corresponding to 700–3000 cm$^{-1}$), and they have corresponding absorption replica at shorter wavelength, equivalent to higher quantum energy or wavenumber. As mid-IR equipment for the wavenumber range of the highest absorption sensitivity is more costly and somewhat more demanding technologically, harmonic lines are used whenever possible. However,
Lasers absorption spectroscopy is a technique for air monitoring by tunable mid-infrared diodes. The figures illustrate molecular absorption lines of HCl at room temperature. The line strength is proportional to the absorption coefficient (and proportional to the absorbed amount of radiation at small absorbances). The strongest absorption and hence the highest detection sensitivity is observed close to 3 µm wavelength around the wavenumber of 3000 cm⁻¹.

Atmospheric analysis typically is very demanding in respect of sensitivity and selectivity, and hence the 700–3000 cm⁻¹ region is used nearly exclusively, because it allows detection limits well below parts per billion (ppb). The qualitative results and conclusions usually hold for the near-IR as well, or are easily adapted.

The heavier molecules have more numerous vibration and rotation freedom and hence more lines than HCl, the example of Figure 1. For typical atmospheric analysis, the lines of the various gas constituents are densely packed (Figure 2) and overlap due to their line width. For this reason, absorption data are usually taken at reduced pressure, so that the pressure broadening is negligible. The residual Doppler width is of the order of some 10⁻³ cm⁻¹, and usually enables a line to be found for detection of a molecule of interest, isolated from the other lines of the atmospheric sample. Doppler broadening is more benevolent to the spectroscopist in that the corresponding line shape drops exponentially from the maximum, whereas pressure broadening leads to an inverse square reduction of the line wings with separation from the line center, and hence leads to more overlap. An example of a problematic mixture is shown in Figure 3. It is obvious, that detection of NO is hindered strongly by overlapping absorptions of the other gas components, that have orders of magnitude higher concentrations. At reduced pressure, the absorption lines are well separated and become accessible to high selectivity and high sensitivity analysis by measurement of spectral absorption.
The key to such an analysis technique is equipment that allows a factor of $10^{-6}$ spectral resolution. Lower resolution would make the low line width absorption advantages inaccessible, as they result in large system line width. Although $10^{-6}$ resolution can be reached with the most sophisticated Fourier spectrometers, such equipment does not allow routine atmospheric analysis because the measurement speed is low and takes hours rather than minutes for most tasks of interest. Diode lasers lend themselves well for atmospheric analysis because they can be made and operated to have corresponding emission band widths and because they are easily tunable by changing the drive current. The principle of operation of a corresponding laser system is simple, as shown in Figure 4. The laser radiation is fed through a sample optical path, and is tuned across absorption lines. This is done in order to discriminate background effects from the absorption line. The laser is tuned repetitively and at high speed, so that any background effects that may vary with temperature are effectively frozen in for a single sweep; single-sweep evaluation and integration for noise reduction then leads to minimum signal drifts.

The true details and operation parameters of such systems are more complicated than the scheme of Figure 4 shows. For instance, the laser power depends on the drive current. From a given threshold current, the laser emits radiation, the intensity of which increases from close to zero to maximum powers of the order of a few 100 µW in the wavenumber range of interest. Laser powers are often specified well above this value and reported to many milliwatts; however, such power levels are gained with laser designs not suited for atmospheric measurement purposes. The increase of laser intensity with drive current gives the baseline without radiation an ascending slope, so that it is not horizontal, as the figure. Various techniques are used to separate the line absorption depression from the baseline variation. One consists of sampling the transmission at the line peak and at two points located symmetrically either side of the line of interest, where negligible absorption is found. The latter are then used to extrapolate the baseline and to determine the base point at the peak.

Another technique consists of modulating the current sinusoidally (or similarly), and then analyzing the transmission signal with a lock-in amplifier tuned to twice the modulation frequency. This method is called 2f method, as many commercial lock-in amplifiers had a special ‘2f’ button for changing from the reference frequency to an internally generated second harmonic. This picks out the curvature of a graph of the spectral transmission curve; that is, the resulting signal is zero for any signal which varies linearly with the wavenumber. As the power ramp is very close to being linear with current (and hence with laser wavelength), this variation is effectively suppressed, and only the extra curvature due to the absorption line shows up in the processed transmission signal.

Another alternative is to record a complete neighborhood of the line under consideration. Then in a second numerical data processing step, a ramp is fitted and subtracted from the data. Within the same procedure, a line fit from stored data can be obtained in order to extract the information of interest – the line position is used for gas recognition and the line strength for concentration measurement. With improving computing power and electronics, this technique is found in an increasing number of laser gas analysis systems.

The lasers have a tuning rate of the order of $0.1–1 \text{ cm}^{-1}$ per milliamp of drive current. This is what makes tuning so easy compared with conventional means, such as rotation of a diffraction grating. However, in order to keep the laser radiation at a stable $10^{-6}$ match to the absorption wavenumber, the current must be stable to within a few microamps.

The laser radiation wavenumber also depends on the laser temperature. This is due to material properties, that inherently depend on the temperature. The laser emission temperature drift is of the order of inverse centimeters per Kelvin temperature drift. As a consequence, laser temperature has to be stabilized to millikelvin levels. As the passive stability due to independent stabilization of the current and temperature is, in most cases, found insufficient for long-term system stability, most laser spectroscopy systems dedicated to atmospheric analysis have active stabilization. This is usually achieved by

---

**Figure 4** Operation principle of a diode laser spectrometer for atmospheric analysis. The laser is tuned by change of its drive current, the laser radiation fed into an optical path through the atmospheric sample of interest, and the laser intensity is recorded as a function of current, thus indicating the concentration of the molecular species of interest by the specific absorption line spectral position and strength.
splitting some of the radiation away from the main beam and guiding it through a reference cell containing the gas of interest in concentrations leading to easily detectable absorption (Figure 5). Electronic or numeric stabilization components evaluate the reference signal and add stabilization currents to the drive current such that the laser radiation always sweeps a well-defined wavenumber range.

Stability is not only limited by laser wavelength drifts. The background spectrum may also change with time. A typical problem of high-sensitivity systems is optical interference due to scattered radiation. Assume for instance that $10^{-8}$ of the power received at the detector is scattered radiation that traveled a distance of a few meters difference to the main beam. The corresponding fields of the direct and scattered beams overlap and give rise to interference structures. The fields vary as the square root of the power, and hence the field modulation is of the order of $10^{-3}$, and comparable $10^{-3}$ modulation is found on the power and the detector signal. Such modulation has periodicities of $10^{-3}$ cm$^{-1}$ for the above mentioned path difference of a few meters, and hence may become similar to the absorption lines. High-sensitivity systems cope with such effects by sequentially filling the sample cell first with nitrogen or synthetic air for background measurement. Synthetic air is preferable, as it resembles atmospheric air more closely and models, for instance, H$_2$O contributions to the transmission interferences. An alternative is scrubbed ambient air, where the species under investigation is removed by a selective scrubber. The second step is filling the sample cell with calibration gas containing the target gas species in low concentration for calibration. Finally, the sample atmosphere is introduced to the cell. This is done automatically, and the final signal is gained from a numerical treatment of all three signal components, which reduces background effects and optimizes calibration stability.

Clearly, the relative presence of spurious signals will limit the detectivity. Generally, the minimum detectable concentration is a direct consequence of the minimum detectable change of the transmission $T$, which is connected to the gas absorption constant $\alpha$ by Lambert–Beer’s law, $T = \exp(-NaL)$. This states that transmission varies with the exponential function of the product of the gas concentration $N$, $\alpha$, and the optical pathlength $L$. One way to optimize sensitivity is to maximize the optical length $L$, a point that is returned to later on. For a given length $L$, the minimum detectable concentration $\Delta N$ is calculated from Lambert–Beer’s law to depend on the minimum detectable transmission change $\Delta T$ by $\Delta N = \ln(\Delta T/\alpha L)$. In typical situations, $\Delta T/\alpha L$ is much smaller than unity, so that as an approximation $\Delta N = \Delta T/\alpha L$ holds well. If one wants to compare system performance for different systems with different optical cell length and different $\Delta T$, one uses a system parameter $\Delta NL$, usually given in the dimension ppm m. This parameter obviously only depends on the gas specific absorption constant and the system transmission resolution.

The minimum detectable transmission change relates directly to the minimum detectable intensity step which is resolvable in the detector signal. In general, this step is equal to the signal noise under operational conditions. The signal noise has various sources, the most prominent of which is the noise of the detector itself. This can be observed with the optical path blocked. This noise is limiting because the power of thermal radiation sources is comparatively low, so that the signal due to spectrally filtered radiation is only some orders of magnitude larger than the detector noise. The optical beam power is proportional to the spectral power of the radiation source and the radiation bandwidth; if one wants to use thermal sources and the $10^{-8}$ spectral resolution that is sought with high sensitivity and high selectivity in mind, then typical integration times in order to get acceptable transmission measurements would be of the order of hours to days, which is totally unacceptable. This is where the high spectral power of diode lasers comes in. In a well-designed laser gas analysis system, the optical power is so high that the signal-to-noise level is no longer dominated by the constant detector noise.

The next noise source to be taken into consideration is the intensity fluctuation due to the laser radiation source itself. This noise is such that $10^{-7}$–$10^{-8}$ signal-to-noise levels can be reached regarding the source only, and this level makes the theoretical sensitivity level for transmission measurements, $\Delta T$, equal to $10^{-7}$–$10^{-8}$. Such signal-to-noise levels have often been
reported by laboratory models of diode laser gas analysis systems. However, realistic systems, as used for atmospheric investigations, never attain such precision due to inevitable adverse environmental parameters such as changing temperatures or acoustic vibrations. At present (and in the foreseeable future) a $\Delta T$ range of $10^{-4} - 10^{-6}$ is realistic. The dominating system noise is usually identified to be the unwanted optical interference signal components discussed above.

In order to give an impression of the sensitivities resulting from such noise levels, typical values are noted in Table 1. These values are theoretical, and derived from the known absorption constants. A $\Delta T$ value of $10^{-4}$ is used; with a very high performance system $\Delta T = 10^{-6}$ can be obtained, which improves sensitivity by a factor of 100. The table is based on absorption data both at the longer wavelengths beyond 3 $\mu$m with optimum sensitivity, and at shorter wavelengths in the near-IR between 1 $\mu$m and 2 $\mu$m which allow the use of more readily available components. The direct comparison shows the sensitivity advantage of the longer-wavelength IR to be 2–5 orders of magnitude. In comparing, note that the numbers are given in ppm for the near-IR and ppb for the mid-IR, a difference of three orders of magnitude.

For the high sensitivities demanded by atmospheric analysis, long optical pathlengths are necessary. There are optical limits to the practical dimensions of the pathlength. Basically, all optical instruments with a long optical path have a radiation source of a given diameter $a$ (or an equivalent internal aperture of diameter $a$), that is matched to the parallel open beam by an optical element with focal length $f$. Even neglecting diffraction, such an element cannot produce a parallel beam; this would only be possible for a light source of zero extension in the focal spot of the collimating optics. The best one can do in real systems is to image the source aperture to a plane at the end of the sample optical path $L$. This image will be magnified by the ratio $L/f$. Let us assume a desirable pathlength of 100 m (typical for high sensitivity atmospheric gas analysis systems), and an aperture $a$ of 1 mm with thermal radiation source. Such an aperture is the lower limit acceptable for optical power reasons. In this case a typical $f = 10$ cm lens will generate an image with $A = 1$ m diameter. The receiving optics thus must be this large in order to catch all the signal power. A laser can be made to have an emitting aperture of some micrometers, which results in an image spot of some millimeters. This is another major advantage of laser transmission spectroscopy.

In practice, beam widths are larger than discussed above for diffraction reasons, but qualitatively the above arguments do hold. As mentioned above, the gas samples should be contained in sample cells that allow a suitable pressure reduction. Such cells must be limited to volumes of some liters, to allow acceptable time constants due to the gas pumping speed. Long pathlengths are obtained by folding the optical beam with mirror systems, so that the gas volume is traversed many times by the beam. Pathlengths of 100 m are readily available, but the above beam-spreading argument also holds for the long-path optical cells that must be very large in diameter for conventional radiation sources. Thus practical considerations regarding closed sample cells also favor strongly the application of diode lasers for spectroscopy.

Long open optical pathlengths in the field are attractive for atmospheric measurements, as the data are representative for a whole area, as compared to sampling the gas locally at the system gas inlet. Also, closed gas sampling systems may induce artefacts; for example, some gases adhere strongly to technical tubing material or the gas cell walls and thus give rise to residual gas concentrations if the gas component is no longer in the ambient air, but freed from the inside walls. As discussed before, cross-sensitivity due to overlapping lines will hinder such measurements at atmospheric pressure. Corresponding data are contained in Table 2. It is worthwhile noting in comparison with Table 1, that $\Delta T$ of the order of some $10^{-5}$ was achieved with the low-pressure systems.

In sum, a typical gas analysis system consists of a radiation source component including temperature control of the lasers. Separate lasers are usually provided for each gas component to be detected. Mid-IR lasers must be operated at low temperatures, typically close to that of liquid nitrogen; appropriate cooling is provided by liquid nitrogen cryostats or closed cycle coolers. The optical beam is formed by mirror optics for minimum unwanted spurious reflections that might originate from lens surfaces. A reference beam with reference cell serves for laser stabilization. The gas cell has a folded optical beam of around 100 m optical pathlength for a cell below a meter in length; the cell volume of one to a few liters allows about one minute gas change times. The detectors are of low noise and usually cooled to below 100 K by standard equipment. Signal analysis and system control by computers is standard. Such systems achieve $10^{-12}$ sensitivities in unattended operation, and $10^{-5}$ for the best routine atmospheric analysis equipment.

### 3 APPLICATIONS

#### 3.1 Review of Monitoring Applications

In recent years TDLAS has found widespread application in the field of atmospheric science. The TDLAS technique meets the major requirements for atmospheric trace gas monitoring: sub-ppb sensitivity, high detection speed, and the potential for simultaneous in situ measurements of several compounds. Researcher laboratories, such as at the Max Planck Institute for Chemistry in Mainz, Germany, have developed own multilaser TDLAS systems and used them extensively for trace gas detection throughout the troposphere and the lower stratosphere on ground-based, ship-based and airborne platforms. Highly specific instruments have been adapted for the direct measurement of trace gas fluxes by the application of micrometeorological techniques and for the measurement of the ratios of the stable isotopomers in methane from various sources.

Operation of these instruments in the field, especially on airborne or ship-based platforms, implies a special design to meet the stringent demands of vibration isolation, shock resistance and weight minimization. Typically, modern systems are computer controlled, multilaser systems which produce pseudosimultaneous measurements on up to four channels by interrogating each laser in turn using different time multiplexing devices.

Table 3 lists trace gases relevant to the chemistry of the atmosphere. Typical mixing ratios for these species in the atmosphere are of the order of ppb ($10^{-9}$) to ppt ($10^{-12}$). The table lists detection limits for a TDLAS field instrument.

</table>

The estimate is based on the system parameters: OD, optical density = 10$^{-5}$; SNR, signal-to-noise ratio = 1; $\Delta f$ = 0.01 Hz (30 s integration time); $L$ = 126 m, $p$ = 30 mbar.
measurement based on a detectable minimum OD of $10^{-5}$. This is a typical in-field sensitivity obtained for high-performance systems. To compare these theoretical estimates based on the line strength of the individual rotational-vibrational transitions, Table 4 lists measured sensitivities for various TDLAS instruments during field employment to detect species with sub-ppb mixing ratios in the atmosphere. In general, there is good agreement between theoretical and deduced detection limits. The table demonstrates that the diode laser atmospheric analysis is highly specific and sufficiently sensitive to measure the concentration of a large number of trace gas species in the atmosphere at sub-ppbv levels.

The inherent capability of the technique to perform high-precision measurements at time resolutions of less than 1 s permits the use of TDLAS systems for airborne tracer measurements to study dynamic processes in the stratosphere (section 3.2) and direct determination of trace gas fluxes by the application of micrometeorological techniques. Trace gas fluxes are commonly deduced from the gas-chromatographic measurement of the concentration increase in closed chambers placed at ground level. The shortcomings of this technique are the limited spatial coverage of the boxes and the uncontrolled disturbance of the ecosystem's microclimate caused by the closed box. To overcome these drawbacks micrometeorological techniques can be applied, such as the eddy covariance technique, which derives the trace gas flux from the covariance between the vertical wind speed and the fluctuations of the trace gas concentration at a given height above the ground. Alternatively the flux gradient technique can be employed, where the trace gas flux is determined from the measured concentration gradient of the emitted trace gas at several different altitudes above the ground and the mean atmospheric transfer coefficient, which can be deduced from momentum and heat flux measurements. The advantage of these techniques is that they average the fluxes over larger areas while not disturbing the microclimate of the ecosystem. In order to make use of such techniques, extremely fast and precise trace gas detectors are needed for eddy covariance measurements, criteria that are both met by TDLAS systems. Tunable diode laser spectroscopy has the potential for eddy covariance measurements of trace gases such as CH$_4$, N$_2$O, CO, NH$_3$, or COS.

Table 4 gives an estimate of quantities relevant to the measurement of fluxes by eddy covariance using a TDLAS, which are the typical ambient air concentration $c$, expected fluxes $F$, absorption line wavelength $\lambda$ and strength $S$, OD at concentration $c$, required as well as measurable precision $R$ and the ratio $r$ of both. The numbers are derived from the formulae given in the table footnote. The measurable precision $R$ is estimated based on the center absorption of Doppler-broadened lines. Typical pressure broadening is represented with a Voigt parameter of 0.5. The Voigt parameter is a measure of the similarity of the line shape to Doppler-broadened line shape or pressure-broadened lineshapes. Intermediate line shapes are said to have a Voigt profile and can be described by a special line-shape formula that makes use of the Voigt parameter. The required $R$ value is estimated from Gaussian error propagation of the covariance of wind and concentration data with neglected wind measurement error. For a half-hour measurement with 10 Hz, the standard deviation of the vertical wind fluctuations is assumed to be 0.2 m s$^{-1}$. Errors introduced by micrometeorological variables are not considered, meaning that the ratio $r$ should be well above unity for satisfactory measurements. Whereas NH$_3$ seems to be detectable from a spectroscopic point of view, COS might be beyond the scope of today’s instruments.

The high selectivity of TDLAS measurements can be used to study the isotope ratios for CH$_4$, N$_2$O,
or O₃. Measurements of the stable isotopomer ratios \(^{13}\text{CH}_4/^{12}\text{CH}_4\) and \(^{12}\text{CH}_3\text{D}/^{12}\text{CH}_4\) in atmospheric methane sources are an important tool with which to establish the global atmospheric methane budget and furthermore provide important information about methane production and consumption processes occurring within the various sources. At the above-mentioned Max Planck Institute, for example, a methane isotope spectrometer (MISOS) based on the TDLAS technique has been developed and directly applied to isotope ratio measurements on environmental samples collected from natural wetlands, rice paddies, landfills, and natural gas. Evaluation of the isotopic composition is based on the simultaneous measurement of a pair of suited absorption lines for \(^{13}\text{CH}_4\) and \(^{12}\text{CH}_4\) or \(^{12}\text{CH}_3\text{D}/^{12}\text{CH}_4\), respectively, which are selected to give similar optical densities on one single laser scan.

The main advantage of the TDLAS instrument, compared to mass spectrometry (MS), is its ability to perform direct measurements on methane samples without the need for any sample preparation (apart from drying) or for chemical conversion of CH₄ to CO₂ and H₂. A comparison between TDLAS and MS-based determinations of the isotopic signature of various samples from natural wetlands, rice paddies, and natural gas. Evaluation of the isotopic composition is based on the simultaneous measurement of a pair of suited absorption lines for \(^{13}\text{CH}_4\) and \(^{12}\text{CH}_3\text{D}/^{12}\text{CH}_4\), respectively, which are selected to give similar optical densities on one single laser scan.

3.2 Airborne Monitoring

3.2.1 Introduction

This section describes as a typical example the set-up and deployment of an aircraft-based tunable diode laser spectrometer which was developed during 1995 and 1996 and which, since early 1997, has been used extensively in a variety of airborne atmospheric measurement campaigns. The TRISTAR (tracer in situ tunable diode laser absorption spectroscope for atmospheric research) instrument has the ability to measure three atmospheric trace gases simultaneously at high time resolutions (below 1 s) using an individual laser diode for each component. The main target species to be measured with TRISTAR are atmospheric components of low chemical reactivity, such as carbon monoxide or nitrous oxide, whose chemical lifetime is comparable or long as compared to that of atmospheric transport or mixing processes. The abundance of these so-called atmospheric tracers and their correlation with each other thus reveals information about the origin of the air mass encountered during the measurement. This information can serve to support other observations of in situ processes, such as atmospheric particle formation, or it can be of principle interest, for example if the nature of atmospheric exchange processes is studied.

In contrast to true atmospheric trace components – chemically active species (such as nitric oxide, formaldehyde, or hydrogen peroxide) with volume mixing ratios usually near or below 1 ppbv – the atmospheric tracers are present in the atmosphere in the range from a few tens to a few hundred ppbv, or even up to 1700 ppbv mixing ratio as in the case of methane. For TRISTAR this implies that the main target species to be measured with TRISTAR are atmospheric components of low chemical reactivity, such as carbon monoxide or nitrous oxide, whose chemical lifetime is comparable or long as compared to that of atmospheric transport or mixing processes. The abundance of these so-called atmospheric tracers and their correlation with each other thus reveals information about the origin of the air mass encountered during the measurement. This information can serve to support other observations of in situ processes, such as atmospheric particle formation, or it can be of principle interest, for example if the nature of atmospheric exchange processes is studied.
In the following, the TRISTAR set-up is described with attention given to the optical, electronic and data acquisition layout of the instrument, the gas flow system which allows in situ calibration, and the data postprocessing that uses the in situ calibration and related diagnostics data. More detailed information can be taken from an instrument-related publication. TRISTAR has been used on two different aircraft types: the German DLR research aircraft Falcon, and a Cessna Citation research aircraft run by the Dutch NLR. Some exemplary results of the measurement campaigns carried out are presented at the end of this section.

3.2.2 Optical Set-up

The optical bench of TRISTAR is a mechanically independent module which can be mounted according to the space requirement of the aircraft used. In the Falcon aircraft, the optics are located on top of a 19 in rack containing the electronics and the gas flow system. Due to the limited cabin height of the Cessna Citation, the optics module is carried by a support structure holding the gas flow system only, with the instrument electronics contained in a separate rack (Figure 6).

Operation of a TDLAS system, especially on an airborne platform, requires careful design to meet the stringent demands of vibration isolation, shock resistance and weight minimization. This affects in particular the optical and mechanical set-up of the system. For TRISTAR a very rigid optical layout was developed consisting of a $60 \times 45 \times 3$ cm$^3$ aluminum board recessed for weight reduction, a single liquid-nitrogen cryostat, housing for three lasers and two detectors, a multi-pass cell based on White’s design, and ellipsoidal, parabolic and plane mirrors for imaging and steering the optical beam. Figure 7 presents a view of the optical bench facing the laser station side of the liquid nitrogen dewar laser cooler.

The principle of operation of the liquid-nitrogen cryostat is based on the evaporation of the liquid nitrogen.
Figure 7  This image of the optical bench is taken from the laser station side of the liquid nitrogen dewar. The three laser cold stations are attached to the base section of the dewar with their lower part partly covered by the mirror objectives that image the emerging beams to an intermediate focus. At the front edge two beam combiners, placed at 45 degrees with their blackened beam dumps can be seen. The right part of the board is occupied by the measurement White cell, whose circular objective mirrors are clearly visible. The detector cold station is mounted on the rear part of the dewar base section, hidden in this image as well as the reference cells.

at the laser/detector cold station. By controlling the flow rate of the evaporated nitrogen the resulting cooling power of each cold station is approximately 1.5 W, independent of the actual operating temperature which can be varied between from near 80 K to 150 K by a heating device. The constant cooling power allows optimization of the electronic temperature controller over the whole operating temperature range of the diode lasers, exhibiting a temperature stability of better than 3 mK. Although the temperature operating point of the three lasers is set in three individual cold stations, the two mercury cadmium telluride detectors are operated in a single station at liquid nitrogen temperature.

Each laser is imaged through a mirror objective onto an intermediate focus producing a real image of the laser front facet. Precise coupling of the laser radiation into the optical path is achieved by aligning the mirror objective in three degrees of freedom, two in the image plane and one in the focal direction, while visually inspecting the front facet image of the laser diode through a crosshair ocular located at the intermediate focus. The rest of the optical path is aligned using visible radiation of a fiber-coupled laser diode, placing the fiber tip at the nominal intermediate focus location. The light emerging from the three intermediate foci is collimated by off-axis paraboloids and combined into a single beam, which is imaged through another intermediate focus into the measurement White cell. This cell contains the sample gas at reduced pressure and provides an optical absorption pathlength of up to 64 m through multiple reflection between the cell front and rear mirror groups spaced 0.5 m from each other. The gold coated mirrors provide reflectivity in excess of 99%. The light emerging from the cell is directed to an exit intermediate focus and then collimated again. The beam is then split with a 50% intensity fraction traversing a chain of reference cells. The cells contain the target gas at high concentration and produce a strong optical absorption signal which is primarily used to stabilize the laser emission wavelengths.

The direct signal and the reference beams are individually focused onto the signal and reference detectors, respectively, by off-axis parabolic mirrors.

3.2.3 Electronics and Data Acquisition

To evaluate the tracer concentration of the gas pumped through the measurement cell, the electronic output from the signal detector is recorded as a function of time while a well defined pulse on the laser current causes the emission wavelength to sweep across the absorption feature. A relative measurement is performed in the sense that this recorded signal is quantitatively related to a corresponding signal resulting from a prior calibration measurement, in which the ambient gas in the measurement cell was replaced by a standard gas of known target gas concentration during a calibration operation.

The key tasks of the instrument electronics and data acquisition are: first, to electronically process the detector signals in order to increase signal-to-noise and signal to background ratios; second, to establish a user interface to set and control the instrumental parameters (such as laser current and temperature), to monitor the absorption signals, and to switch either manually or through a predefined time schedule between measurement and calibration mode; third, to stabilize the laser emission wavelength to the absorption line by the determination of shifts in the spectral signal of the reference detector and corresponding minute variations to the laser current pulse and/or the laser operating temperature; and fourth, to analyze the spectral signals in real time deducing the trace gas mixing ratio and an error estimate from the measured absorption spectra by comparison to the spectrum recorded in the preceding calibration. The last task is governed by the conditions of the measurement situation – at typical aircraft speeds of 50–200 m s⁻¹ a measurement time resolution of approximately 1 s is required to obtain adequate spatial resolution. For a typical measurement flight lasting 3–4 h it would be impractical to store all the spectral data for a later off-line analysis, and furthermore the opportunity to monitor the
measured trace gas concentration on-line during flight is of great advantage for the mission, allowing other activities to be triggered, such as to perform grab sample measurements or to even modify the planned mission schedule in case of unexpected events.

The TRISTAR electronic layout is shown in Figure 8. All electronic subunits are controlled by a digital signal processor (DSP) housed within an Intel 80486-based personal computer (PC), except for the diode laser controller. The laser bias current and temperature are set via a standard laboratory IEEE 488 link. To increase the signal-to-noise and signal to background ratios a phase-sensitive detection scheme is implemented. The optical frequency emitted by a tunable diode laser can be modulated efficiently up to the radiofrequency (RF) range by adding an electrical RF signal into the laser current. The optical sidebands produced by the frequency modulation of the laser are balanced in the absence of differential optical absorption. The absorption feature destroys this balance, resulting in an RF signal on the detector which is phase coupled to the RF laser feeding signal and thereby can easily be demodulated (lock-in technique). By this method, the signal generation is shifted in a frequency regime where laser, detector and electronic noise are significantly reduced due to the component’s 1/f frequency characteristic. In the two-tone frequency modulation technique used here, an electronic modulator on the laser side creates two RF signals, typically 105 MHz and 125 MHz, that are added to the laser current. On the detector side the signal is retrieved by demodulators (individually for the optical signal and reference paths) at the laser signals’ frequency difference of 20 MHz. This technique offers some advantage in the reduction of the background signal caused by spurious laser amplitude modulation as compared to the method where a single RF signal is used for modulation and demodulation.

The high demodulation frequency also allows fast sampling of the absorption signals and thereby fast scanning of the laser emission across the absorption lines. To allow simultaneous measurement of the three target species, the three lasers are sequentially pulsed for 2 ms each with an individual pulse shape for each laser generated by the DSP. During the scan the absorption signal is recorded at a sampling rate of 100 kHz, while at the same time the preceding scan is processed. This includes an algorithm that determines the line peak position from the reference detector signal and imposes the adequate correction in the signal averaging and for the next pulse of that laser, following 6 ms later (line locking). Time-multiplexed absorption signals are thus averaged for all three lasers in basically the same timeframe, which is determined by the PC and synchronized to the aircraft board time.

Typically each full second the PC requests a data analysis from the DSP, which automatically starts a new signal integration. For the data analysis, the DSP optionally smooths the spectrum. If necessary, a background spectrum previously generated with neutral gas (dry nitrogen) in the measurement cell is subtracted and the resulting spectrum is used as a target for a linear least-squares fit of the calibration spectrum and a second-order polynomial. The fit parameters are converted to concentration values using the known mixing ratio of the

![Figure 8](image-url) The electronic set-up of TRISTAR.
calibration gas, and transferred to the PC together with items of diagnostic data. The most important of these is a measure of the laser power determined from the detector signal difference sampled between the scan end and a subsequent 0.1 ms gap time, in which all lasers are off, i.e. not pulsed. While the averaged spectra and the resulting trace gas concentration values and their time series are displayed on the PC screen, the DSP generates the sampled signal waveforms on analog outputs to be displayed on an oscilloscope for diagnostic purpose. The calibration spectra, trace gas concentrations and diagnostic data are stored on the PC hard disk.

3.2.4 Gas Flow and Calibration

The ambient air is conducted to the measurement cell by a gas sampling system which is fully included in the calibration, as indicated in Figure 9. The air is sampled with an inlet directed against the flight direction from outside the aircraft boundary layer through a 0.5 in PFA tube and expanded into the measurement cell through an adjustable critical orifice, which keeps the cell pressure at approximately 40 hPa independent from the outside pressure. The sample air is driven through the cell by a 16 m³ h⁻¹ rotary pump at the cell exit. With the cell volume of 2.7 L a gas exchange time of 1 s is achieved. The calibrations are performed at intervals of 10–20 min depending on the flight schedule and typically last for less than 1 min. For this purpose, an excess flow of the calibration gas is introduced very close to the outside end of the intake line, with the surplus gas ejected outwards. A gas tank of compressed air provides nitrous oxide, carbon monoxide and methane at ground-level ambient mixing ratios which are calibrated before and after the measurement campaigns to a primary gas standard traced to a standard from the National Institute of Standards and Technology (NIST, Gaithersburg, USA).

The calibration system is also prepared for sticky or reactive gases such as H₂O₂, HCl, or HNO₃, using the constant mass flow of permeation sources. For stable operation of the permeation devices constant purging is required, and the gas lines need conditioning. Therefore, a continuous low gas flow is driven from the tank through the devices, circulated close to the calibration gas injection point of the sampling line and removed by the rotary pump when ambient air is measured. For calibration, a valve in the pump line is closed and the gas is added to the high flow of calibration gas from the tank. With this approach, no valves need to be placed remote from the instrument at the intake point or between the permeation sources and the calibration gas inlet, and possible loss of the calibration gas caused by wall reactions are minimized.

3.2.5 Data Postprocessing

To assure the quality of the measured data, the calibration spectra are analyzed on the ground. During a flight typically 10–20 calibration spectra are generated for each species. First, the line shape and shift of the spectra are inspected to ensure that the line locking procedure worked correctly and that the laser operating point was stable. Then, the signal height change is analyzed by a linear fit of each calibration spectrum to its successor. The deviation of the fit result from unity identifies the instrumental responsivity drift during the time interval between the two calibrations. Correlating this deviation with the corresponding deviation in the measured laser power reveals whether power changes caused the drift. These changes may arise from minute alterations in the optical alignment, due for instance to temperature changes in the cabin or in certain cases from changes in the composition of cabin air, which changes broad-band absorption in the optical path outside the measurement cell. A clear correlation between sensitivity and measured laser power will only arise if the laser operates on a single mode which, although desirable,
is not always achievable with the lasers available. In the case of single-mode laser operation, the data quality can be improved by appropriate normalization of the raw data to the laser power. For multimode operation, a drift in sensitivity between two successive calibrations is not necessarily correlated with the power signal. For multimode operation and mode competition noise, the drift appears to be of stochastic origin, and a linear time interpolation for the instrument response between two successive calibrations is carried out. Typically these corrections are smaller than 2%, which is the precision that can be quoted for the measurement data.

Since 1998 a further diagnostic parameter has been introduced by applying the same fit algorithm that is used to determine the ambient gas concentration from the signal spectrum to the reference channel. In multimode operation of the laser, the mode spacing is large compared to the absorption linewidth, therefore the fit result is a direct measure of the laser power present in the measurement mode – provided that the absorption in the reference cell is stable and large compared to the measurement cell, which in general is the case. The beam splitter separating signal and reference channel is placed behind the White cell, so changes in alignment or in mode competition affect both channels equally and the data can be normalized to the relative power of the measurement mode deduced from the fit of the reference cell signal.

The most prominent aspect of the data postprocessing is that drift-induced level shifts of the measured concentration time series before and after a calibration are significantly reduced. The calibrations are usually performed during stable phases of the mission schedule when no sudden change in the atmospheric concentration is expected.

3.2.6 Field Deployment

The TRISTAR system has been installed on the German research aircraft Falcon operated by the DLR, Oberpfaffenfalen, and the Dutch research aircraft Cessna Citation II operated by the Technical University of Delft and used during a total of six field missions in the years 1997 to 1999 to study dynamical and chemical processes in the atmosphere up to 13.5 km altitude. A first scientific mission with the Falcon was undertaken from Kiruna (Northern Sweden) to study the trace gas composition of the upper troposphere and stratosphere, the development of hygropause clouds and particle formation in lee-waves (the POLSTAR mission). The TRISTAR system was used successfully to perform high-precision tracer measurements (N\textsubscript{2}O, CO) in the tropopause region. Additional CO and N\textsubscript{2}O measurements with TRISTAR, were obtained in March 1997 during the European Community-funded STREAM (stratopause troposphere experiments by aircraft measurements) campaign in Kiruna. Successful operation of all three channels (CO, CH\textsubscript{4}, N\textsubscript{2}O) was achieved during the second Arctic POLSTAR expedition in January 1998. Further campaigns with the Cessna followed in March 1998 (LBA-CLAIRE: cooperative LBA airborne regional experiment) to study trace gas emissions over the Amazon, July 1998 (STREAM-Canada) to study biomass burning of the boreal forest in Canada, and in February–March 1999 during the Indian Ocean Experiment (INDOEX) to study trace gas distribution and transport associated with the Indian winter monsoon. Within these missions TRISTAR provided a large amount of trace gas measurements in the tropopause region in tropical, mid and high latitudes. These data give a wealth of information on chemical and dynamical processes that influence the chemical composition of the upper troposphere and lower stratosphere.

As an example Figure 10 shows measurements of N\textsubscript{2}O and CO in the Arctic winter lower stratosphere obtained during the POLSTAR and STREAM expeditions in January and March 1997, respectively. Both species have sources in the troposphere and major sinks in the stratosphere, leading to nearly constant mixing ratios in the upper troposphere and decreasing concentrations in the lower stratosphere. The mixing ratio of N\textsubscript{2}O in the troposphere measured during both campaigns is constant at a level of approximately 312 ppbv. The average free tropospheric CO concentration measured during the STREAM winter campaign in March 1997 was 147 ± 8 ppbv. This is significantly lower than CO concentrations measured 2 months earlier in the same location during the POLSTAR campaign. During POLSTAR average free tropospheric concentrations were 168 ± 18 ppbv. Above the tropopause N\textsubscript{2}O and CO exhibit decreasing concentrations with increasing altitude. Although the altitude profile for N\textsubscript{2}O is similar for both campaigns, CO

![Figure 10](image-url) Average CO concentration as a function of N\textsubscript{2}O for STREAM (filled triangles) and POLSTAR (open squares) data. The CO data have been binned according to N\textsubscript{2}O. Notice that the two correlations have been shifted by 1 ppbv against each other on the x-axis to avoid overlap of data points in the figure.
shows a temporal trend towards lower concentrations in the lower stratosphere, similar to the trend observed in the troposphere. So the CO concentrations on the highest flight levels ($N_2O = 275–280$ ppbv) during POLSTAR were of the order of $30–35$ ppbv, comparable to earlier observations, whereas CO concentrations at similar altitudes during STREAM decreased to $20–25$ ppbv.

The general trend of decreasing CO concentrations in the lower stratosphere between January 97 (POLSTAR) and March 97 (STREAM) could be due to a seasonal increase of the OH radical concentration, leading to a higher CO loss rate later in the year. Observations demonstrate that tropospheric CO exhibits a strong latitude-dependent seasonal cycle, with CO enhancements of up to $100$ ppbv at high northern latitudes in the winter compared to the summertime minimum. This seasonal variation, whose amplitude decreases with decreasing latitude, is mainly due to the seasonal variation of the OH concentration. It must be assumed, that the increase of the OH concentration from January to March will also influence the CO concentrations in the lower stratosphere, and can thus at least partly explain the observed temporal trend between POLSTAR and STREAM. In addition, mixing processes have to be taken into account, in particular transport of CO-poor air from the tropical tropopause region.

### 3.3 Rocket-based Experiments

#### 3.3.1 Introduction

In the 1990s a tunable diode laser spectrometer was designed, built and tested to be flown on a sounding rocket in order to measure the abundance of water vapor and carbon dioxide in the upper atmosphere. This instrument was named MASERATI (middle-atmosphere spectrometric experiment on rockets for analysis of trace-gas influences). Details on the technical aspects of this instrument and first scientific results from the two rocket flights performed in 1998/99 have been published. In the following discussion the most important scientific and technical aspects are summarized.

High-resolution in situ measurements of $H_2O$ and CO$_2$ in the mesosphere and lower thermosphere (the atmosphere region from approximately 50 to 120 km above sea level) are of importance for our understanding of the atmosphere. The concentration of water vapor in the upper atmosphere is critically determined by photochemical processes and by transport through convection, advection, and turbulence. Therefore, a measured water vapor profile allows for a sensitive test of theoretical models that combine both atmospheric dynamics and chemistry. During summer, the existence of various layers such as noctilucent clouds and polar mesosphere summer echoes is controlled by the concentration of water vapor and temperature.

Despite their scientific importance, in situ measurements of water vapor are rather sparse and contradictory. Remote sensing by ground- or satellite-based techniques cannot achieve the spatial and temporal resolution required to study small-scale processes. Mass spectrometers have been flown on sounding rockets, but cannot be used for water vapor, as this trace gas (as do others), reacts with the surfaces inside the mass spectrometer which causes an unknown modification of the mixing ratio. In summary, there is a lack of data on the concentration of water vapor, and simultaneous studies of water vapor profiles and turbulence have not been performed at all before.

Carbon dioxide may serve as a reference for water vapor measurements in order to deduce mixing ratios from number densities. Carbon dioxide is an appropriate reference as its concentration is constant from the ground up to 90–95 km, as has been shown by in situ and satellite measurements. Above 95 km the CO$_2$ mixing ratio decreases rapidly due to photochemical destruction and demixing by molecular diffusion. Apart from being a reference for the H$_2$O measurements, the carbon dioxide profile is of interest on its own account.

From the decrease of the CO$_2$ mixing ratio with altitude, one can deduce the turbopause altitude and the mean turbulent mixing coefficient, also called the ‘eddy diffusion coefficient’, $K$. Model studies have shown that the mixing ratio of an inert tracer around the turbopause reflects the long-term effect of turbulent mixing and vertical convection. This may be very different from the actual turbulence field encountered during the rocket flight. In addition to $K$, one can also deduce actual turbulent parameters, such as turbulent energy dissipation rates, from the small-scale fluctuations of the carbon dioxide mixing ratios. The underlying idea of this analysis and the results from recent neutral gas density measurements are described in the literature. The combined measurement of CO$_2$ and H$_2$O allows an interesting comparison between the long-term mixing effect and the actual strength of turbulence measured during flight.

Carbon dioxide is the major coolant of the upper atmosphere due to excitations of the CO$_2$ molecules by collisions and subsequent emission of IR radiation. The efficiency of this cooling strongly depends on the excitation/deexcitation mechanism of the CO$_2$ molecules, thus on the coupling between the radiation field and the gas. As the lifetime of the excited states is of comparable magnitude to the mean time between collisions the CO$_2$ molecules may not be in local thermodynamic equilibrium (LTE). It turns out that collisions with atomic oxygen are most important for the radiative
coupling between CO$_2$ and the background atmosphere. Non-LTE of CO$_2$ has been investigated with models and measurements for several years, but there are still large uncertainties regarding the quantitative effect of non-LTE on the CO$_2$ cooling rate. The problem is the measurement of the deactivation coefficient $k_O$ of atomic oxygen on carbon dioxide at realistic temperatures, and the uncertainty of the actual atomic oxygen number density $O$. Diode laser spectroscopy can be a tool to measure non-LTE effects directly by studying two appropriate CO$_2$ absorption lines simultaneously. From this, one can determine the vibrational temperature of the excited level $T_{vib}$ which deviates significantly from the kinetic temperature $T_{kin}$ if CO$_2$ is not in LTE with the environment. In Figure 11 we show model calculations demonstrating the difference between the vibrational and the kinetic temperature under non-LTE conditions. The kinetic temperature profile used in these calculations exhibits wavy fluctuations, as expected during a flight performed in the winter season. As explained in more detail elsewhere, the non-LTE effect is enhanced if the temperature profile is disturbed, for example by gravity waves. The intercomparison of $T_{vib}$ and $T_{kin}$ allows for a determination of the product $k_0 \cdot O$, which is exactly the quantity needed to estimate the radiative cooling efficiency of CO$_2$.

3.3.2 Middle-atmosphere Spectrometric Experiment on Rockets for Analysis of Trace-gas Influences: A Rocket-based Tunable Diode Laser Spectrometer

In order to perform measurements described in the previous section, a dedicated diode laser system was designed, built, and tested. Two IR diode lasers are mounted on a cold head which is cooled by liquid nitrogen. The operating temperature of each laser is around 80–120 K and is stabilized to within a few millikelvin. For reasons explained in more detail elsewhere, laser emission lines at 1559.06 cm$^{-1}$ (i.e. in the 6.5 µm band) for water vapor, and at 2347.57 cm$^{-1}$ (i.e. in the 4.3 µm band) for carbon dioxide were chosen.

Part of the laser beam is directed through a reference cell containing both carbon dioxide and water vapor. The absorption signals from this reference cell are used for laser stabilization and monitoring. The main part of the laser beam is directed into a multipath absorption cell (White cell) which is open to the atmospheric environment. The optical cell is mounted in front of the rocket payload, so that the atmosphere is sampled without the risk of contamination due to gases leaking from the rocket body. Inside the White cell the laser beam is reflected 104 times which results in a total pathlength of 32 m.

Both lasers are operated sequentially, i.e. one laser is turned off while the other is emitting. The switch over from one laser to the other occurs every 7.37 ms. While one laser is emitting, its frequency is tuned by varying the injection current in order to scan the absorption line. A small modulation with high frequency (500 kHz) is superimposed on the laser current which leads to a corresponding modulation of the laser frequency. The absorption signal is detected at the second harmonic of the modulation frequency by a lock-in amplifier in order to improve the SNR. The laser spectrometer was designed to be able to detect gases with a relative absorbance as low as $10^{-4}$–$10^{-5}$ for an integration period of approximately 1 s. The height resolution at the expected payload speed of 1000 m s$^{-1}$ varies from a few meters for CO$_2$ (no integration required) to about 1 km at the upper altitude limit (integration period 1 s).

An instrument to be flown on a sounding rocket has to be specially designed, qualified and tested in order to survive the large mechanical stress in the acceleration phase of the flight. It must be ruggedly constructed and minimized in terms of weight and dimensions. Table 6 gives more details on the mechanical specifications of MASERATI. The MASERATI instrument consists of

three main mechanical subsystems: the White cell, the laser and detector section, and the electronics section (Figure 12). A photo of the MASERATI section is shown in Figure 13.

The basic details of the three sections are as follows: The White cell (No. 8 on Figure 12) ensures a long optical path to maximize absorption with minimum physical space. The total optical path in the White cell is 32 m. The White cell is built in an open configuration, that is, with direct contact to the ambient air (no tubing, valves etc.). It is placed at a considerable distance (336 mm) from the base deck in order to minimize shock-front effects. Aerodynamical calculations were performed to demonstrate that under flight conditions the major part of the shock front is located behind, i.e. downstream of, the White cell. One therefore expects very little influence from shock front effects on the measurements and practically no contamination from outgassing of the payload.

The laser section (No. 9) contains the two tunable diode lasers, the optics for laser monitoring and stabilization (power and frequency), and the detectors for the reference and the White cell signals. It also contains the liquid nitrogen dewar for cooling of the lasers and the detectors. The dewar has a maximum capacity of 2 L which corresponds to a maximum operation time of approximately 6 h. Figure 14 shows a photo of the rear end of the laser section.

The electronics section (No. 10 on Figure 12) contains various power supplies, digital and analog electronics for laser current and temperature control, lock-in amplifiers, and analog and digital interfaces to the control computers. The 2f signals are amplified with an automatic gain adjusted to the actual signal strength. The largest available gain factor is \(2^{14} = 16384\).

The laser and the electronics sections are sealed to ensure that no seawater can enter the payload when it is floating in the ocean after flight waiting for recovery. The White cell is located underneath the rocket nosecone and is covered by a separate hood (No. 7) to be protected during lift-off and during the first phase of the rocket flight. The hood is vacuum tight, and on the ground the gas composition and pressure can be controlled from outside which allows to test and monitor the laser performance during tests and countdown. The hood is mechanically fixed to the nosecone; both are ejected at approximately 50 km on the upleg part of the rocket flight.

In the MASERATI electronic section the raw data received from the detectors are amplified and preprocessed. Only the important information is stored and used for later data evaluation. The absorption spectra and various other data that monitor the performance of the instrument (e.g. the laser temperatures) are digitized in the MASERATI electronic section and are then transferred to the so-called housekeeping section of the payload (No. 3) where the data are transmitted to the ground by means of standard telemetry techniques. The most important parameters of the electronics are listed in Table 7.

The MASERATI instrument is mounted on top of a sounding rocket called RONALD, a German–Norwegian collaborative project for middle-atmosphere studies. The payload is equipped with a sea recovery unit (No. 4) which basically consists of a parachute and a floatation bag. The parachute ensures deceleration before impact, and the floatation bag prevents the payload from sinking. A beacon and a strobe light are mounted on top of the floatation bag to help locate the payload in the ocean. The recovery unit also contains a despin mechanism which reduces the spin of the payload during flight from 3 Hz to practically zero (the residual spin during the first flight was 0.1 Hz). The total weight of the rocket is 1.5 metric tons, the payload weight is approximately 300 kg. The total length of the rocket is 8.6 m, nearly half of which (4.3 m) consists of the rocket motor (No. 6) and the conical adapter (No. 5; Figure 12). The diameters of the payload and the motor are 44 cm and 56 cm, respectively.

A sounding rocket launch is a strong mechanical burden for a complicated instrument. In the initial phase of the rocket flight (for about 26 s after lift-off), there is a nearly constant acceleration of 6–10 g superimposed by strong vibrations. After motor burn-out, accelerations are very small. The rocket motor transports the payload to an apogee of about 120 km within 170 s. The payload falls into the sea approximately 7.5 min after lift-off.

3.3.3 Laboratory Calibrations, Environmental Tests, and First Results

A special vacuum chamber had to be set-up in the laboratory to test the sensor in the pressure range from \(10^{-6}\) to 10 mbar. The instrument was calibrated with a wide range of \(\text{CO}_2\) and \(\text{H}_2\text{O}\) mixing ratios, total pressures, and gas temperatures. Several calibration

Apart from MASERATI (1) the other main instrument on board the payload is TROLL (transmitter and receiver of laser light)\(^\text{20}\) (2). Furthermore, the payload consists of a telemetry section (3) and a recovery unit (4). A conical adapter (5) is used as an interface between the payload and the rocket motor. (6) More details on the MASERATI instrument are given in the text.
series were performed to study and maximize the SNR and to determine the absolute sensitivity of the instrument.

One can only dare fly such a singular and costly experiment on a rocket after extended simulations have been performed, for instance regarding the pressure changes expected during flight. The instrumental parameters must be chosen carefully because they cannot be changed during the rocket flight. The laboratory tests demonstrated the sensitivity of MASERATI to be in the range $10^{-4} - 10^{-5}$ of relative absorbance for an integration time of 1 s.\(^{(27)}\) This corresponds to an upper altitude limit of 120 km and 95 km for CO\(_2\) and H\(_2\)O, respectively, taking into account the expected concentrations, the performance of the particular lasers, and the selected spectral lines. Concerning the small-scale fluctuations in the CO\(_2\) channel, the noise at high sampling rates was also analyzed at signal strengths which correspond...
to mesospheric altitudes. Random noise fluctuations of 0.5% (root mean square) for sampling rates of 14 ms were measured which is sufficient to detect turbulence-induced density fluctuations. Several vibration tests with accelerations expected during the rocket flight were performed for various subsystems as well as for the entire instrument. After minor problems were identified and solved the instrument was found to be well suited for a sounding rocket flight.

MASERATI was launched twice from the Andoya Rocket Range (69°N) which is located on an island in northern Norway. The first flight took place on October 12, 1997, at 01:19:00 UT under perfect operational conditions, i.e. no troposphere clouds, very little ground wind, no aurora. The rocket reached an apogee of 120.9 km. Other ground-based and rocket-borne instruments were in operation in order to independently determine atmospheric parameters such as densities and temperatures in the mesosphere.

In Figure 15 a sequence of $2f$ signals from the reference channel and from the White cell channel is shown, which had been measured during an early stage of the first flight when the acceleration of the rocket is still about $6g$ and the spin is 3 Hz (the de-spin of the payload occurs later during flight, some 48 s after lift-off). At this time the White cell is still tightly surrounded by the vacuum cover. In both channels (reference and White cell) there are two CO$_2$ absorption signals which originate from lines at 2347.58 cm$^{-1}$ and 2347.63 cm$^{-1}$, respectively. The corresponding line strengths $S$ at room temperature are $6.8 \times 10^{-19}$ and $1.3 \times 10^{-19}$ cm per molecule, respectively. The ratios of the $2f$ signals in Figure 15 differ from the ratio of $S$ due to two effects: the second CO$_2$ $2f$ signal in the scan is given preference relative to the first by optimizing the amplitude of the frequency modulation for the second line, as it is weaker compared to the first; in addition, the absorption in the reference cell is close to saturation (the amount of CO$_2$ in the reference cell is rather large in order to get a strong signal, used for laser stabilization).

The second MASERATI flight took place on January 31, 1998, at 23:43 UT. In Figure 16 a sequence of scans of the CO$_2$ channel is shown as measured during flight in the lower mesosphere at approximately 66–67 km. Very persistent and stable spectra are observed which confirms the good technical performance of the instrument. More details on this flight are available.\(^{(27)}\)

Unfortunately, there was a failure in the rocket hardware which prevented the payloads from being recovered from the sea. Still, the MASERATI instruments have demonstrated the suitability of the TDLAS technique for in situ measurements in the mesosphere and lower thermosphere on board sounding rockets.

### 3.4 Exhaust Gas Analysis

#### 3.4.1 Introduction

In the field of exhaust gas analysis, tunable diode laser spectroscopy has been applied both to the analysis of stack gas of power plants\(^{(37)}\) and to automotive exhaust within industrial test beds. In the latter case, two different directions were followed. On one hand, a couple of exhaust gas components were measured simultaneously for both Otto engines\(^{(38)}\) and Diesel engines\(^{(39)}\) with response times of the order of 1 s. A special version, equipped with a long-path cell, for detection limits down to ppb levels was also reported.\(^{(40)}\) On the other hand, fast response gas analysis with response time distinctly lower than 1 ms, but with lower sensitivities, was demonstrated in the early 1980s.\(^{(41,42)}\) Later developments\(^{(43,44)}\) led to more sophisticated systems with a response time of the order of 5 ms.\(^{(44)}\)
Modern cars are characterized by remarkably low exhaust gas emission levels, essentially realized by improved engine design and by sophisticated exhaust gas after-treatment. As a result, the emission contributions of state-of-the-art vehicles mainly occur at cold-start and during nonstationary operational phases. Better control of these two conditions represents the major potential for further emission reductions.

3.4.2 Dynamic Car Exhaust Gas Analysis: The Diode Laser System

Figure 17 is the block diagram of the optics and the electronics of a dynamic car exhaust gas analyser system. Two IR diode lasers are operated at a precisely controlled individual temperature ($\Delta T = 3$ mK) and current ($\Delta I = 10 \mu$A). Both laser beams are combined at first to form one beam and then split in order to generate one reference and two measurement channels with respective detector elements and further signal processing units. All set-points and control-circuits are microcomputer-controlled and can be operated from a PC located up to 20m away from the instrument.

The diode lasers are operated by applying current pulses of typical 60$\mu$s duration in time multiplex with a repetition rate of 5 kHz. The concentration is evaluated after each pulse.

The principle of fast gas sampling is given in Figure 18. Two sampling channels are incorporated in parallel into the system in order to extract sample gas at two locations out of the car exhaust gas line. Due to the special geometry at the cell and the low-pressure conditions, no particle filter is required, thus preventing unwanted sample gas delays. The exhaust gas, taken from a selected position of the car exhaust gas system, is fed into the 2 mm inner diameter tube of a coaxial heat exchanger approximately...
100 cm in length, with a counterstream of pressurized air at 190 °C in the outer jacket. The sample gas is then fed into the temperature-controlled sample cell, which has a length of 30 cm and a diameter of 0.6 cm. The pressure in the cell is kept at 50 mbar by a large buffer volume, which is common to both sampling channels. Pressure control is achieved by means of a fast butterfly valve between the buffer vessel and the pump, the latter having a relatively large pumping capacity of 60 m³ h⁻¹. The fast sample gas velocity within the heat exchanger results in a delay along the sampling system of about 20 ms. It has been found that the turbulent flow of the sample gas does not intermix the gas significantly; therefore, variations in composition are transferred to the sample cell without noticeable modification.

The system response time is essentially determined by the gas exchange time in the sample cell. The windows of the sample cells are made of sapphire, which can be easily interchanged or cleaned if necessary. Under practical operating conditions, cleaning is required once a day. Even Diesel engine exhaust gas with a high particle content can be analyzed for more than half an hour before cleaning of the windows is required.

Figure 19 gives a view of the analyzer system taken during a measurement campaign. In the rear, a large Diesel engine can be seen. The laser spectrometer optics are located on the left side of the black upper portion, with a liquid nitrogen cooler dewar protruding on the top. Below on the left are laser operating and data processing electronics. To its right, the sample gas conditioning system with the pressure control and pump (at the bottom) can be seen. The two sampling lines with integrated heat exchangers are on top of the right side; they lead directly to the sample cells, which are not visible. The sampling lines can be rotated to come as close as possible to the sampling location. In order to extract the exhaust gas sample, welded pipe sockets at the respective positions of the exhaust gas line of the engine are required. Flexible connections between the engine and analyzer are obtained with short 2 mm stainless steel tubes and standard Swagelok components.

The major specifications of the analyzer are listed in Table 8. The instrument has been conceived for two exhaust gas components which are measured simultaneously at two sampling locations, yielding a total of

four real-time values of concentrations. Four molecular species (Table 8) have been determined so far. The detection limit values are obtained with selected strong (with the exception of CO₂) absorption lines of the respective molecular species which do not overlap with those of other exhaust gas components. This is a prerequisite for gas analysis free of cross-interference.

System calibration and zeroing is performed by flooding the total car exhaust gas pipe by a sufficiently high flow of test gas and zero gas, respectively. This way not only the spectroscopic part of the instrument, but also the complete sampling system is included in the calibration procedure. In our experience, one calibration cycle per day is sufficient.

3.4.3 Results of Dynamic Car Exhaust Gas Analysis

The results discussed below were obtained during a number of measurement campaigns by European and US American automotive companies. Although most of the results were classified as proprietary to the respective companies, a few findings can be given in order to illustrate the potential of tunable diode lasers in fast exhaust gas analysis.

The first two examples were obtained with a single-cylinder research engine. In Figure 20 the NO and CO emissions are plotted as measured simultaneously behind two different outlet valves at an engine revolution rate of 2000 rpm. The SNR of the analyzer is better than 50:1 under these conditions, which means that the observed variations in Figure 20 represent real concentration profiles. The cylinder pressure is given for reference.

As can be seen, the time constant is sufficient to resolve each cycle; even faster variations can be distinguished. Note that the emissions of NO at the two outlet valves are largely synchronous, whereas the CO values exhibit distinct differences. This behavior indicates inhomogeneous combustion due to improper air–fuel mixing. Such facts are not observable using conventional exhaust gas techniques. This kind of result is extremely helpful when testing detailed combustion models and to optimize the combustion in experimental engines.

Another result obtained with this single-cylinder engine is given in Figure 21. It represents a comparison between the NO emission measured directly with 0.8 s averaging time as well as with a commercial chemoluminescence (CLD) system with approximately 0.8 s response time. For the plot, the time delay between both measurements was corrected. The ignition was turned off for approximately 1 s in order to intentionally generate a strong transient. The variations observed with the ignition turned on are again essentially not due to noise but represent real fluctuations of NO level. The noise level of some 150 ppm can be deduced from variations during the ignition-off period.

![Figure 20](image)

![Figure 21](image)

Figure 21 Comparison of NO concentrations as measured by the system of Figure 19 (DEGAS III) and by a CLD instrument with approximately 0.8 s rise time. (Reproduced by courtesy of Renault, Direction de la Recherche, Rueil Malmaison.)

The overall agreement between the two curves taken with the 0.8 s time constant is excellent, although the CLD under these conditions yields some more
information, including a step pattern connected to the single combustion cycles. Obviously, the dynamic analyzer with full time resolution provides considerable additional information as compared to the CLD. In addition to the fluctuations mentioned there a large peak upon turn-on, which may point to an unusual high temperature during the first combustion cycle. The corresponding results for CO, not shown here, exhibit a similar fine structure with a somewhat poorer agreement for the 0.8 s average with respect to a conventional measurement with nondispersive IR techniques.

A further investigation concentrated on the influence of fuel composition on the emissions as a function of crank angle. Figure 22 is an example for CO and CH₄ emissions obtained for a four-valve single-cylinder engine under stationary operation. The temporal profiles of these two exhaust components were required in order to test different thermodynamic models of the combustion process. The cylinder pressure was again recorded for reference. The data were synchronously averaged over a number of strokes in order to produce a sufficiently high SNR for the relatively low CH₄ emission values. By this procedure, repetitive features in every stroke can still be distinguished with full system time resolution. To obtain the graph in Figure 22, the time delay of the gas measurement was again compensated.

Figure 23 is an example for a Diesel engine measurement. Plotted are the NO and CO concentrations emitted from one cylinder of a six-cylinder 14.6 L engine in stationary operation at about 1400 rpm. The upper two traces show the valve control signals and the cylinder pressure, respectively. Whereas the NO concentration proceeds quite regularly from cycle to cycle, the CO emission exhibits distinct irregularities. During zero CO emission periods, the residual noise during this measurement of about 50 ppm may even lead to a negative reading, as seen at 0.45 s.

The result shown in Figure 23 for an engine running at a relatively low revolution rate illustrates that high time resolution yields valuable information even in the case of stationary engine operation. In this particular case, the resolution is high enough to observe non-reproducible
structures within single combustion cycles. During this investigation, the effect of modifications to the engine management was often observed on-line in the emission concentrations.

The above examples show that dynamic car exhaust gas analysis by tunable diode lasers is a valuable tool in engine research as well as in engine development and fine tuning. A net advantage at present seems to be in the investigation of instationary engine operation and the corresponding emissions; these may exhibit millisecond emission peaks that can considerably contribute to the total emission, such as over a driving cycle. A detailed interpretation of the results requires additional information on the engine operation parameters and the gas flow dynamics in the cylinder and the exhaust system. The benefit is not only a better knowledge of the behavior of individual engines, with the potential of efficient optimization of the engine operating parameters, but also a better understanding of the combustion thermodynamics within the cylinder. The first can be immediately transformed to higher fuel economy and lower emission of existing engines, the latter will have an appreciable impact on future engine development.

4 RELEVANT SYSTEM PARAMETERS

4.1 Gas Handling

Sampling systems usually consist of the intake and a tube connecting it to the sampling cell. These parts require special attention if the target molecules adsorb to the walls, or if they react with or on the walls. This can only be accounted for by proper choice of the wall material and by sufficient air flux through the intake system.

The same holds for the sample cell itself. Choice of materials is limited here, as the optical windows and optical components needed inside long-path cells must be of good optical quality. However, very rarely is a satisfying compromise not found. These material problems are not specific to laser systems, but are found for nearly all analysis systems except open optical path systems. Most other analysis techniques face stronger sampling restrictions.

Long optical pathlengths are necessary in order to obtain high sensitivity. For low concentrations and consequently low absorptions, the measurement signal (which is the reduction of the transmission) is proportional to the pathlength. For a length of more than some meters, long-pathlength cells with folded optical beams are inevitable. Such cells scale in length proportional to the optical path. The partial beams are stacked side by side, so that the cross-section of the cell is filled proportionally to the number of partial beams. As the number of partial beams again is proportional to the whole length, the cell cross-section area scales with the number of beams, and hence the cell volume scales with the square of the optical beam length and thus with the square of system sensitivity. This discussion neglects the fact that the beams expand within the cells, which asks for increased cell diameters proportional to the cell length. This results in an overall increase of cell volume with the third power of the pathlength (and third power of sensitivity, too). In practical cases, very small cells are often limited in volume by other technical demands; cell volumes of commercial cells range from a few tens of milliliters for a 3 m cell to some liters for a 100 m optical path.

Trace gas analysis typically requires an optical pathlength of 100 m, which results in gas exchange times of the order of many seconds, depending on the pump efficiency and the cell design. The gas throughput is about two orders of magnitude smaller, due to the reduced pressure in the sampling system, so that the total gas throughput is quite limited and usually of no concern.

For calibration purposes, one usually flushes the whole intake system, so that all wall effects enter into the calibration and need not be corrected later on. Systems with very high sensitivity are usually operated by probing consecutively a calibration gas, then zero gas, and finally the atmospheric sample, as discussed in section 2. Thus system drifts can be accounted for. The total time for taking a data point this way is of the order of 1 min.

The temporal resolution of the reduced sensitivity emission analysis is also limited by the gas exchange, which was reduced down to the order of milliseconds by proper sample cell design. Open-path measurements can be much faster, the sampling time being limited by the acceptable noise which in general is the product of the system noise level and the signal averaging bandwidth. This may be of importance for model studies of atmospheric reactions at higher reaction rates; the system time constants are quite easily brought down to the order of microseconds and below.

4.2 Diode Lasers

The characteristics of these components are dominant on system design and performance, an exception being optical interference features that are common to all tunable laser spectroscopy systems.

Diode lasers are usually made from semiconductor wafers a few hundred micrometers thick, by cleaving or breaking them into small cubes, the laser chips. Two faces of these cubes serve as mirrors for the laser resonator; sometimes they are given optical coatings to optimize the resonator properties. Two laser chip faces perpendicular to the resonator mirror facets are contacted and (usually) soldered to electrical connections. One of
these also acts as a heat sink. This is necessary, since the delicate semiconductor–metal contacts have to sustain current densities up to \(10 \text{kA cm}^{-2}\); most of this current is converted to Joulian heat, which must be led away to prevent the laser from overheating.

The active layer producing the radiation usually has a thickness of the order of a fraction of the radiation wavelength and is located parallel to one of the contact faces, and a few micrometers below it. This face usually is located close to the heat sink, as the active layer produces most of the energy losses and must be well cooled. Typical dimensions of mid-IR lasers are some \(300 \mu\text{m} \times 300 \mu\text{m}\) in length and width (of the contact plane) and \(300 \mu\text{m}\) in thickness (Figure 24).

Most lasers have active layers that are limited to a narrow stripe of some micrometers to some tens of micrometers so as to confine the laser radiation to only one propagation direction.

Figure 25 is of a mid-IR laser diode, showing the diode in its mount. The chip can be seen in the reflection of the crystal facet behind the laser. The crystal is PbSe, and the laser chips are made of wafers cut from such crystals parallel to the crystal facet. The PbSe material is a member of the IV–VI semiconductor family. At present, IV–VI diode lasers are available commercially for the 3–15 \(\mu\text{m}\) wavelength range, and are used nearly exclusively for atmospheric gas analysis.

As a voltage is applied to the laser, a current can be observed that is typical of the current–voltage characteristics of a rectifying diode. This is because the active area giving optical gain has an internal p–n junction. To generate laser radiation, the diode is driven in forward direction so that the electrons of the n-type material and holes, the charge carriers in the p-type material, recombine near the p–n junction. One of the recombination channels effects spontaneous emission of photons that carry the difference in energy between the conduction band and the valence band, \(E_g\). These photons can be observed by a detector that detects radiation coming from the facet and near the p–n junction. The intensity of this radiation increases with current, as expected from the increasing number of carriers that recombine. A faster increase of the emission with current results, due to stimulated emission, and finally an even stronger and nearly linear increase occurs which is combined with a high coherence of the radiation, the laser emission. The output power \(P\) of a diode laser is usually described as an approximately linear function of current, \(P \propto (I - I_{th})\), with \(I_{th}\) being the threshold current. This power usually is comparatively low, and in usable lasers can be up to some 100 \(\mu\text{W}\). This is moderate compared to other wavelength ranges and other laser types. However, the spectral power is orders of magnitude larger than what is available from conventional blackbody sources. This is one major advantage of diode laser systems as compared to conventional IR spectroscopic systems.

The second advantage stems from the fact that the refractive index of the laser material depends on temperature. As the geometrical dimensions vary negligibly with temperature, the change of refractive index causes the optical length of the laser resonator to vary. This length determines the emission wavelength, because a multiple of half the emission wavelength must fit into the resonator length. As mentioned before, most of the laser current is lost and transformed to heat generated in the active section. This heat changes the temperature which in turn results in a variation of the emission wavelength. Hence the lasers are tuned by the current, which gives a very fast and efficient tuning mechanism that is optimally suited for electronic control.
For technical reasons, diode lasers mostly are made of double hetero structures, with a thin active semiconductor layer embedded between different (passive) semiconductors. This active layer is where the carriers are made to recombine and add their energy to the laser radiation. The active layer is also designed to guide the radiation. Thus the output area has a thickness of the order of the thickness of this layer. In practice, the output area has about the height of a wavelength and a width of one to several wavelengths. The radiation coming from such an aperture is governed by diffraction effects such as radiation originating from a narrow slit. The corresponding diffraction lobe of the lasers is elliptic, usually with a strong difference between the two diameters of the ellipse. It is hard to cope with such strongly divergent beams; the optical situation is analogous to that of a microscope objective. Usually a high aperture is sought for the first optical system, the laser collimator. Most optics use off-axis paraboloids or ellipsoids for the first nonplanar mirrors. The following beam diameter is usually chosen to be of the order of 2 cm, or larger for laboratory systems with reduced stability and mobility demands. This diameter is one influence on the total system dimensions. As diffraction-limited beam sizes scale proportionally to the wavelength, one must always expect long-wavelength IR optics to have larger dimensions than optical systems for visible light.

On its path from the laser through the system optics and sample cell to the detector, a number of optical elements have to be traversed (windows and lenses) or touched (mirrors). As a number of different wavelengths are used for different target components, all lens systems have to be corrected to a high chromatic tolerance. This is difficult to accomplish for the IR range. Moreover, all surfaces give rise to reflections and scattering. Such spurious radiation gets onto the detector and leads to interference, as discussed in section 1. Typically, interferences fluctuate with time and give rise to optical system noise on the detector signal, which limits system sensitivity.

The lasers are also sources of noise, as the laser emission has some residual fluctuation. When close to mode hops (described below), this noise may be large and dominant. Usually, however, a free-running laser that is well protected from beam reflections has a noise floor that does not limit the system sensitivity. Reflections into the laser are another type of interference noise, which must be minimized in order to retain system sensitivity. For this reason, all optical elements are usually made from mirrors rather than lenses.

The optical gain within the laser has a limited bandwidth of some 10 cm\(^{-1}\). As stated before, a multiple of half the laser radiation wavelength must fit into the laser resonator. This can be fulfilled with a number of different wavelengths. The emission can hence consist of many different electric field configurations called modes, with different wavelengths. The mode spacing usually is given in wavenumbers, \(\Delta \nu = 1/(2nL)\), where \(L\) is the length of the resonator (some 100 \(\mu m\)) and \(n\) is the refractive index. Typically, such modes have separations of the order of inverse centimeters, and many modes may be emitted.

As the laser material changes its temperature, the gain band also changes its wavelength location. It does so at roughly fourfold the tuning rate of the modes. Hence, single modes have varying gain, as their wavelength position changes relative to the gain band. The usable tuning length of a single mode is from one to a few inverse centimeters. In general, therefore, laser diodes are selected for wavenumber bands that correspond to the specific substances to be analysed. Whenever a mode dies out as a result of tuning, due to insufficient gain, and a new mode is observed, one talks of mode hops.

Close to such mode hops, the laser power fluctuations increase and may dominate the system noise. Figure 26 shows mode spectra of a mid-IR diode laser. The spectra are taken at the same laser operating temperature, but in two different operating current ranges as evidenced by the different wavenumber ranges emitted. These spectra have remarkably few modes and relatively high powers, which shows that they were well selected.

Single-mode lasers can be made by special external optics or by special laser structures. The latter are usually periodic structures along the laser resonator, and corresponding lasers are called distributed feedback (DFB) or distributed Bragg reflector (DBR) lasers, dependent on the specific design of corrugation. Such lasers have been demonstrated for the wavelengths of interest by laser developers, but have reached production stage. This is mainly because diode laser gas analysis is a limited market that cannot support the development of a specific laser technology.

In summary, the diode laser technology and characteristics strongly influence the system design. The small laser emission bandwidths that are possible allow for good selectivity. Their fast tuning response is the basis of high system stability, as the absorption lines can be scanned rapidly, absorption features determined for each scan, and then averaged, a procedure that eliminates drifts. Multimode emission is often found and is detrimental to system performance. Specific combinations of laser current and temperature are usually sought, that reduce these detrimental mode effects such that they do not govern system performance.

Diode laser technology is more advanced at wavelengths of interest for telecommunications. These are in the near-IR and are made from the III–V semiconductors, such as GaAs. Both DFB and DBR lasers are available with 1.54 \(\mu m\) emission for use in gas analysis systems. Such equipment can be bought for emission control of NH\(_3\).
in power stations with catalytic NO conversion. As the achievable sensitivity is strongly limited by the reduced absorption coefficients at such small wavelengths, the advantages of the short-wavelength technology are not available to most atmospheric analysis tasks.

At the time of writing (1999), a new laser type, the so-called quantum cascade lasers, has become available in some laser development laboratories. They make use of some technology features developed for short-wavelength III–V lasers. The major difference to the IV–VI diode lasers are their higher powers. Their operation temperatures are higher in pulsed mode, and lower in continuous mode, which is the mode used in most air monitoring systems. The tuning characteristics are

---

**Figure 26** Mode spectra of a mid-IR diode laser. The spectra were gained by recording emission spectra at a temperature of 124 K and two laser operating currents around 450 mA (a), and 300 mA (b). Spectra were taken for variable currents indicated on the vertical axis, and spectral positions with laser mode emission are indicated in the figure by vertical bars that are proportional in length to the mode powers. The relative amount of power in the leading mode and the total mode power are listed. (Courtesy of laser components, a producer of mid-IR lasers).
quite different, in that tuning by current is much slower. If used in an air-monitoring system, this imposes much less burden on temperature and current stability, but leads to larger power increase with tuning, which in turn burdens the techniques needed in order to discriminate absorption effects. Lasers of this type are at present not used in air-monitoring systems.

4.3 Conclusions

Diode laser gas analysis systems for air monitoring have sample cells 10–100 m in optical length and one to some liters in volume. The air is kept inside at reduced pressures close to 30 mbar, so that in the common flow-through mode only a negligible volume of air is sampled. System time constants are in minutes for very high sensitivity measurements with complete sample–calibration gas–background gas sequences. If fast measurement is sought, the air is directly sucked through the long path cell, and the time constants are of the order of seconds. System response times for very fast measurements at reduced sensitivity are still limited by the gas exchange time, although orders of milliseconds are achieved. If the air sample does not have to be changed, the system time constant is limited by the available laser power and detector time constants, and microseconds are reported.

Nearly all smaller molecules of interest can be monitored. Notable exceptions are all gases with vanishing or very small permanent dipole moments, such as N₂ and O₂. In general, no pretreatment of gas samples is needed. Only if heavily contaminated samples have to be treated, for instance due to soot or corrosive components, are the optical surfaces of mirrors and windows cause for concern. The measurement process itself is usually not affected by admixtures in air monitoring samples.

Optically, the bandwidth is of the order of $10^{-5} - 10^{-6}$ of the wavelength. This high spectral resolution is needed for low-pressure spectroscopy; this is less critical at ambient pressure, but at the price of reduced sensitivity and selectivity. Single lasers are operated to scan intervals of $10^{-2}$ to about one cm⁻¹; scan times vary from some microseconds to milliseconds.

5 COMPARISON TO OTHER GAS-MONITORING METHODS

As a rule of thumb, whenever small to medium size molecules are to be analyzed with high temporal resolution, high sensitivity, high selectivity, and with quantitative comparison – all at the same time – the diode laser technique is very well suited. The major disadvantage at present lies in the price and sometimes the size of such equipment. Additionally, for highest performance, as is often needed in atmospheric analysis, skilled operation is required.

The most commonly used gas-monitoring methods are chemical in nature. Air samples are fed through volumes filled with sensitive materials that respond to specific molecules, for instance with a color change. These techniques are relatively inexpensive and the necessary equipment can be stored at locations of interest; however, they do not give exact quantitative results and can only be used once. Hence they are not suited to monitoring applications.

Similar arguments hold for sampling with enrichment and subsequent transfer to a laboratory. Again, only singular detections are possible; however, collection can be performed over prolonged time intervals, so that mean values can be determined. Although the collection step limits this technique, be it temporal resolution or possible chemical reactions between sampling and analysis, this type of analysis is very sensitive, very selective, and can be performed on a large number of compounds. Additionally, such analyses are capable of detecting large molecules such as polychlorinated biphenyls, which are not accessible to laser gas analysis in their typical atmospheric concentrations. As a rule for atmospheric analysis, laboratory techniques of this type and diode laser spectroscopy do not compete directly; if both are accessible there will be a clear decision, dependent on the technical and scientific goal.

Typical air-monitoring techniques are CLD for nitrogen oxides and flame ionization detection (FID) for hydrocarbons. Both are proven and their use is widespread. The disadvantages of both as compared to the laser technique is their limited selectivity; improved selectivity always stems from additional sample treatment. Although these are standard analysis techniques, their different operation principles and sample treatments can lead to different systematic errors, and hence they only give limited bases for detailed theoretical conclusions on atmospheric chemistry. The laser technique is advantageous in this regard, because it detects the different gas components with the same principle and from only one sample, which is not affected by the analysis technique itself.

Conventional spectroscopic techniques are also used for air monitoring. Nondispersive and filter techniques use large-bandwidth spectra compared to laser spectroscopy. Such systems are quite rugged and are standard for CO₂, for instance. Although useful for many applications, disadvantages lie in their limited sensitivity, selectivity, and multicomponent ability. IR spectroscopy is used frequently. If used with comparable optical pathlength and hence comparable potential sensitivities, these instruments suffer from the low intensity of their conventional
radiation sources, which makes large detector time constants necessary. In principle, IR systems exist that have the same $10^{-6}$ spectral resolution as diode laser spectroscopy. However, such systems are quite costly and bulky, can only be operated in laboratory environments, and have spectrum recording times of the order of an hour. This makes them a very good tool for gaining high-resolution reference spectra, but does not allow routine atmospheric analysis.

The final point about the analysis of clean air is the use of spectroscopic equipment with open-path measurement. In this case, the radiation is made to travel a considerable distance through the atmosphere, so that high sensitivity is gained. Measurements yield a column concentration, which is the average of the concentration along the optical path which may be as long as 1 km. Depending on the application, this may be an advantage or a disadvantage over local sampling. In general, open-path techniques can be performed both with diode laser spectroscopy and with conventional spectroscopy. The advantages of laser systems are higher sensitivity and higher measurement speed, whereas conventional systems offer better multicomponent capability. Both lack superior spectral resolution due to pressure broadening.

The discussion so far concentrates on a "clean" atmosphere. Close to pollution emitters, the situation is different, in that higher concentrations of many compounds make cross-sensitivity a problem; problems must also be expected from other contaminants, such as particulates. As an example, consider exhaust gas analysis. Standard techniques for car exhaust gas measurement essentially are influenced by the Californian legislation for the reduction of detrimental exhaust components. Established techniques for single components in exhaust gases are FID for hydrocarbons, CLD for nitrogen oxides and nondispersive IR analysis for gases such as carbon monoxide. Their underlying physical principles make these techniques unsuitable for multicomponent analysis and their sensitivities do not satisfy the increasing analytical requirements. In addition, FID cannot resolve individual hydrocarbons and the contribution to the signal to some extent depends on the compound itself and on the composition of the gas matrix. This matrix dependence is far more important than in clean air.

The analytical results obtained from single-component methods are not strictly comparable because the sample-conditioning procedures differ considerably from component to component. For example, CLD detection of NO requires an admixture of dried ambient air after separation of particles in order to generate excited NO$_2$ molecules from NO and oxygen and to subsequently determine the ultraviolet light emission. If, in addition, NO$_2$ has to be determined, an additional catalytic converter is required to reduce NO$_2$ to NO. The NO$_2$ concentration is then determined only indirectly, i.e. as the difference. Such gas-conditioning processes essentially determine the temporal response. In general, the temporal behavior is not strictly comparable to that of other gas components which are measured by other techniques, such as by FID with corresponding sample conditioning, including particle filtering and the admixture of other gases. Different sample-conditioning procedures potentially also result in different chemical reactions within the sample gas, which may lead to systematic errors that are difficult to identify.

Instruments for Fourier transform infrared (FTIR) analysis of exhaust gas have only been commercially available since the late 1990s. They enable selective analysis of various exhaust gas components and allow for temporal resolution in seconds, all with a common sampling technique. The FTIR technique enables the measurements of exhaust gas components in those spectral ranges where absorption by water vapor is weak. Whereas inorganic exhaust components can be detected in a reliable manner, detection of individual hydrocarbons is possible only in some cases. The absorption bands around a wavelength of 3 µm allow detection of the sum of hydrocarbons; however, this also depends on the type of fuel. In practice, different analytical wavenumbers and band widths are used for petrol and diesel fuel. The FTIR technique therefore replaces the conventional techniques, with comparable results. Its noise-equivalent concentration limit is commonly accepted to be of the order of 1 ppm, which is mainly due to its limited selectivity. This degree of sensitivity, together with its relatively poor time resolution, make FTIR inadequate to meet the needs of car exhaust gas analysis in motor development.

One prime advantage of FTIR is its high calibration stability, which is a consequence of the IR detection principle. This property is also expected to hold for the IR diode laser technique. Moreover, FTIR has proved, that superimposed IR spectra can be evaluated very reliably by numerical methods. In principle, these properties will also hold for IR diode laser spectroscopy, and the more complex laser absorption signature is expected to achieve selective resolution of a large number of organic molecules.

An increasingly popular method is chemical ionization mass spectroscopy (CIMS), based on selective chemical reactions of added gases, which are selected according to the exhaust gas component to be detected. The method is characterized by extreme sensitivity, multicomponent capability and high speed of response if applied to a single component. Stability of the signal is a problem, because it depends on the ion yield and hence also on the exhaust gas composition. As a result of the insufficient mass resolution, the necessary
selectivity can be achieved only by special ionization. Exhaust gas components with similar ionization energy and similar mass cannot be separated. These problems can be handled, if only classes of compounds as different hydrocarbons are measured.

Mass spectroscopy with preceding laser excitation\(^{48}\) can in principle yield similar sensitivities to CIMS, but is limited by the number of available lasers with the required high power. Multicomponent analysis requires specific wavelengths for single groups of exhaust gas components, which are only partly achieved by fixed-frequency lasers, and are realized for example by using tunable dye lasers. The high expense for such lasers, if they are feasible, does not permit their economical operation under engine test bed conditions.

For scientific investigations, other methods have been successfully applied. Among these are nonlinear optical methods, such as coherent Raman spectroscopy;\(^{49}\) This technique enables high spatial resolution, high selectivity, and high speed of measurement. For routine operation with test beds, this method is supposed to be too complex at present. Further problems originate in the high laser power levels under field conditions and in the skilled manpower requirement for operation. The same can be stated for other laser techniques that rely on nonlinear optics. They may represent an optimum choice for specific scientific investigations, but are not suited as universal methods for the large number of compounds that need to be analyzed with typical test beds for engine development.

In summary, many measurement systems are used for air monitoring. At the present state of development, system price and the demand for trained operators often are the main arguments against buying equipment using mid-IR diode laser spectroscopy for air monitoring. Technically and scientifically this technique is definitely superior to the others, whenever multicomponent measurement (with a limited number of separate components) is needed, with at the same time high selectivity, high absolute correctness, and high measurement speed.

### ABBREVIATIONS AND ACRONYMS

- **CIMS**: Chemical Ionization Mass Spectroscopy
- **CLD**: Chemoluminescence
- **DBR**: Distributed Bragg Reflector
- **DFB**: Distributed Feedback
- **DSP**: Digital Signal Processor
- **FID**: Flame Ionization Detection

A wide variety of optical- and laser-based techniques have been and are currently being investigated as means of identifying and characterizing explosive materials. These efforts are hampered by the very low volatility of explosive compounds at room temperature and their tendency to ignite at higher temperatures where their vapor pressures are beginning to reach a regime where the species can be readily detected. Traditional, condensed-phase absorption spectroscopy (both infrared (IR) and ultraviolet/visible (UV/VIS)) requires larger samples than are frequently available and, although useful as confirmatory techniques, do not provide signatures that enable unique identification of species. The choice of nontraditional techniques for analysis of explosive materials is dependent upon the amount of sample available, the sample matrix, and sample-imposed constraints upon the measurement. Raman spectroscopy can identify and quantify condensed-phase explosive materials, but the detection limit depends upon substrate, excitation wavelength, and illumination area: limits of detection (LODs) vary from 0.05 ng for 2,4,6-trinitrotoluene (TNT) on glass to 10 µg for nitroglycerin (NG) on silica gel. The other detection techniques considered require volatilization of either the explosive compound itself or more often of characteristic decomposition products, such as NO, NO₂, or N₂O. Using IR irradiation, researchers have demonstrated that photoacoustic spectroscopy (PAS) has detection limits ranging from 0.55 ppb (parts per billion) for vapor-phase NG with 9 µm excitation to 220 ppm (parts per million) for vapor-phase 2,4-dinitrotoluene (DNT) with 6-µm excitation. IR laser differential absorption detection of dissociation products NO, NO₂, and/or N₂O can achieve detection limits of a few picograms. Laser-induced fluorescence (LIF) detection of the photofragments (typically NO) of explosive compounds yields detection limits in the tens to hundreds of ppb (by weight) range. Low LODs can be achieved using ion detection techniques: resonance-enhanced multiphoton ionization (REMPI) spectrometry is capable of LODs for detecting vapor-phase explosives compounds in the hundredths to tens of ppb range; ion mobility spectrometry (IMS) has vapor-phase detection limits for common explosive compounds of typically 200 pg, but for some species can be significantly lower: for example, 1 pg for TNT.

1 INTRODUCTION

Chemical detection and analysis of explosives is playing an increasingly important role in the modern world.

1. Criminal investigations of a bombing require forensic identification of the explosive materials involved in order to provide information on who the perpetrators may be and ultimately to link suspects with the type of explosive materials used. The thermal instability of most explosive materials leaves very little of the original explosive material following an explosion. Thus detection and identification of explosive residues on debris materials is very difficult. Consequently high detection sensitivity is required for successful analysis.

2. Detection of explosive materials concealed in mail or in airline baggage is also important in order to prevent crimes. Highly sensitive instruments capable of detecting explosives in air sampled from mail or baggage is required. Since identification can
be hindered by the use of less common explosive materials; the repertoire of species detected needs to be expanded.

3. Since composition variation affects stability, detonation sensitivity, ignitability, and performance of explosives, accurate knowledge of the exact composition of explosive materials is important for their safe handling and storage.

4. Analyses may be necessary in order to address environmental and/or health-related concerns. Because many explosive materials exhibit some toxicity, ingestion or inhalation of explosive materials presents a significant health hazard. Sites where analysis may be required include industrial facilities where explosive materials are manufactured in order to insure the safety of the workers and of nearby residents. In addition, sites may have become contaminated by improper storage or disposal of explosive materials, and analysis may be required as part of an environmental clean-up of the area.

2 PHYSICAL AND CHEMICAL PROPERTIES OF EXPLOSIVES

The chemistry of decomposition of explosive materials has been extensively investigated with many efforts still on-going. We will concentrate on those physical and chemical properties of explosives that are pertinent to their detection and characterization.

Laser-based explosive detection involves recording information on the intensity and wavelengths of characteristic absorptions and/or emissions of samples that may contain explosive materials. It is the physical and chemical properties of the explosives that govern or constrain the methods and techniques of laser-based detection. Most laser-based techniques focus on vapor and/or particle detection and were developed from knowledge of molecular properties and spectroscopic signatures of the target.

Explosives are categorized or distinguished by their chemical structure. They can be divided into the following groups: nitro compounds; nitriti esters; nitramines; salts of nitric, chloric, and perchloric acids; azides and other compounds capable of exploding; and mixtures. Nitro compounds are distinguished by the carbon–nitrogen bond (C–NO2). Most compounds which have three or more nitro groups for one benzene ring and some which have two nitro groups (dinitrobenzenes and dinitrotoluenes) are used as explosives. Nitric esters are characterized by the presence of a nitroxy group —C—O—NO2. This means the nitro group in nitric esters is attached to a carbon atom by means of an oxygen atom. Nitrarnines are characterized by nitro groups attached to carbon atoms via a bridging nitrogen atom —C—N—NO2. They are basically derivatives of the simple inorganic nitramine NH2NO2. Salts of nitric, chloric, and perchloric acids can be used as explosives or in explosive mixtures as oxygen carriers. Azides include compounds such as hydrazoic acid (HN3), lead azide (Pb(N3)2), and silver azide (AgN3). Other compounds such as fulminates and diazo compounds also fall under this category. Mixtures are simply common explosives combined to obtain the required characteristics.

Hence most organic compound explosives have a chemical structure with a bound NO2 functional group and are subdivided by which atom attaches to this group. Table 1 lists properties for five common explosives with this property. (For more information about other explosive materials, see Urbanski and Köhler and Meyer.) The several different methods of measuring these properties have led to several different values, especially for vapor pressures. The vapor detection methods are limited because the room temperature vapor pressures of these explosives are small. There is a large increase in vapor pressure at elevated temperatures, but other properties such as ignition temperature limit the maximum detection temperature and introduce various dangers. Also, explosives undergo various physical and/or chemical changes at these elevated temperatures. Table 1 lists equations used to calculate the vapor pressure

3 FUNDAMENTAL CHARACTERISTICS

3.1 Effects of Physical Variables

For each of the situations requiring explosive analysis, the explosives may react with and be affected by their environment. Detection of explosives in open air and in underwater environments provides significant challenges when compared with detection in buildings or vehicles. Many detection techniques employ in situ or noncontact measurements and applications often require sensor mobility, minimal sensor size/weight, and unique processing methods. Detection systems must be sensitive enough to find small amounts hidden in a complex environment, and must be able to discriminate between threatening and harmless materials.

Explosive detection devices must be designed differently for different threats. Aviation security, law enforcement, counterterrorism, process quality, health safety, and environmental remediation groups require widely different instruments and techniques. For explosives detection, the largest physical barrier is the method by which the explosive sample is collected.

There are primarily two methods for introducing the sample to the detector: vapor or particle sampling. There are also two distinct techniques, portal screening (a fixed installed sampler) and portable/hand-held samplers. Portals are designed to sample explosives mainly from people. They use techniques such as vacuums, high-velocity airflow, wiping, or a combination of these. Portable or hand-held samplers are used in the field or a laboratory to collect samples from the ground, groundwater, or atmosphere.

There are several orders of magnitude difference between the density of a solid explosive sample and a typical saturated explosive vapor. Hence detection methods for solid-phase explosives may require only a microscopic sample, while vapor detection requires a large sampling volume and methods to increase vapor pressure and overcome the strong surface adsorption of these vapors by the transport mechanism. Vapor sampling is also limited because many explosives are deliberately concealed or sealed and the vapors may be attenuated or adsorbed by the containment materials.

3.2 Analytical Considerations

Factors affecting the detection limits include sample purity and sample thermal history. To produce readily useable commercial and military devices, explosives are commonly mixed with binders, such as waxes, thermoplastics, or rubbers. This has the effect of reducing the relative amount of explosive present. If macroscopic quantities of sample are available, then chemical and/or physical separation may be necessary prior to analysis. Subjecting explosive materials to heating may induce physical and/or chemical changes in the substances; thus the characteristic spectroscopic signatures may be different depending upon the amount and extent of heating.

3.2.1 Solid Sample Mixtures

Explosive material molecules tend to cling tightly to surfaces. Handling of explosives is sufficient to transfer detectable amounts of explosive materials to hands and subsequently to other surfaces touched by hands. In the case of RDX, eight consecutive hand washings with soap and water were required before the RDX could no longer be detected on the hands. Although the vapor pressure is very low at room temperature, TNT has been shown to contaminate surfaces (such as wood, rubber, aluminum) placed near, but not touching the TNT. In the case of porous materials such as wood, significant TNT contamination was found not only on the surface, but throughout the wood. This tendency of explosive materials to spread can be an advantage for forensic investigations and for efforts to prevent terrorist activities. However, it also implies that great care must be taken to insure that any explosive material detected is from the sample of interest and not from previous contaminated samples (memory effects), from other samples stored in the laboratory, or from handling of the sample.

With regard to forensic investigations or efforts to prevent terrorism, one of the primary difficulties is locating the small samples (often milligrams or less) that might be located on a large item. As noted above, this search is hindered by the very low vapor pressures of most explosive materials at room temperature. Once located, the investigator must decide whether to attempt analysis in situ or to separate the explosive from the matrix by heating or chemical means. The advantage of analyzing the sample in situ is that there is no loss to adhesion to sampling apparatus walls or to thermal degradation. The disadvantage of analyzing in situ is that the presence of other compounds may preclude definitive identification and quantification. Preconcentration may be required for successful detection. With regard to analyses for process control or to address environmental or health-related concerns, analyses are subject to the usual concerns about how to representatively sample (heterogeneous) solid mixtures.
Solid mixture samples can be characterized using IR spectroscopy, Raman spectroscopy, UV/Vis spectroscopy, and fluorescence spectroscopy. Vaporization or solvation of the sample also allows these and other techniques to be employed. As mentioned above, the use of chemical or physical separation facilitates definitive identification and quantification.

### 3.2.2 Liquid Mixture Samples

In principle, liquid mixture samples are the easiest to analyze since: (1) chemical separation prior to analysis is facilitated in the liquid phase and the results of analysis of purified samples are more definitive than those of mixtures; (2) preconcentration techniques are simple for liquid mixtures; (3) liquids avoid the difficulties arising from low vapor pressures; and (4) several of the techniques require the sample to be introduced as a liquid. In practice, the presence of liquids interferes with detection by some of the techniques, for example, LIF where water quenches the fluorescence of explosive materials.

### 3.2.3 Gas-phase Mixture Samples

A major difficulty in measurement of gas-phase explosives arises from their pronounced tendency to stick to surfaces, especially when metal surfaces are present. This can preclude accurate determination of the vapor pressure because, even for the case of an in situ sample, the vapor pressure will equilibrate between the rate of vaporization and the rate of plating out.

Calibration is one of the most important parts in verifying or developing any analytical technique. For calibration, one requires a standard source to produce with good precision a known amount of analyte. Several research groups have reported vapor generator calibration sources for explosive materials. Pella constructed a vapor generator for TNT, DNT, and ethylene glycol dinitrate (EGDN), obtaining concentrations as low as 0.05 ppb with a systematic error within 15 to 20% of the values expected for TNT. He was able to generate an equilibrium vapor concentration of the explosive at a known temperature by passing N2 through a column containing explosives. Gas chromatography was used to evaluate the operation of this system.

Davies et al. have designed and calibrated a pulsed vapor generator for TNT, RDX, and PETN (Figure 1). The pulsed generator could deliver between 1 and 1000 pg of explosive in a pulse of less than 5-s duration with outputs within ±20% of the expected value. Their vapor generator had four main components: a temperature-controlled explosives vapor reservoir; a flow control manifold; thermostated air supply; and data acquisition and control system. The explosives reservoir contained ~0.1 g of solid explosive suspended on quartz beads. The temperature of the explosives reservoir was monitored by two thermocouples and controlled to within ±0.1°C by controlling the flow rate of the cooling and heating air. A nichrome wire heater was used to keep the outlet temperature 4 ± 1°C higher than rest of the generator to avoid the deposition of explosive vapors at the outlet. The carrier gas was controlled by valve V-1.

A three-way solenoid valve SV-1 was used to switch the flow of carrier gas between set-up manifold and the generator coil. During initial set-up and between explosive vapor pulses, the carrier gas flowed through the set-up manifold. In order to calibrate the vapor generator, calibration, one requires a standard source to produce with good precision a known amount of analyte. Several research groups have reported vapor generator calibration sources for explosive materials. Pella (19) constructed a vapor generator for TNT, DNT, and ethylene glycol dinitrate (EGDN), obtaining concentrations as low as 0.05 ppb with a systematic error within 15 to 20% of the values expected for TNT. He was able to generate an equilibrium vapor concentration of the explosive at a known temperature by passing N2 through a column containing explosives. Gas chromatography was used to evaluate the operation of this system.

Davies et al. (20) have designed and calibrated a pulsed vapor generator for TNT, RDX, and PETN (Figure 1). The pulsed generator could deliver between 1 and 1000 pg of explosive in a pulse of less than 5-s duration with outputs within ±20% of the expected value. Their vapor generator had four main components: a temperature-controlled explosives vapor reservoir; a flow control manifold; thermostated air supply; and data acquisition and control system. The explosives reservoir contained ~0.1 g of solid explosive suspended on quartz beads. The temperature of the explosives reservoir was monitored by two thermocouples and controlled to within ±0.1°C by controlling the flow rate of the cooling and heating air. A nichrome wire heater was used to keep the outlet temperature 4 ± 1°C higher than rest of the generator to avoid the deposition of explosive vapors at the outlet. The carrier gas was controlled by valve V-1.

A three-way solenoid valve SV-1 was used to switch the flow of carrier gas between set-up manifold and the generator coil. During initial set-up and between explosive vapor pulses, the carrier gas flowed through the set-up manifold. In order to calibrate the vapor generator,
they collected explosive vapors in vapor collection tubes; the samples were subsequently transferred to an ion mobility spectrometer (see section 4.6.1) for quantification.

Eiceman et al. have tested and characterized a vapor generator for TNT, RDX, and PETN from 79 to 150°C. The mass output rate was stable for several hundreds of hours. This instrument was calibrated using the National Institute of Standards and Technology (NIST) gravimetric method. The mass flow rates of TNT and RDX were consistent whereas PETN was higher. This is due to molecular decomposition of PETN at higher temperature. The vapor output of TNT and RDX was in pure molecular form in the operating range (79–150°C) of the instrument. This system was good for calibrations involving TNT or RDX, but had limited use for PETN.

### 3.3 Interferences

All techniques are potentially subject to interferences that can result in an incorrect determination of a species’ concentration. There are several types of possible interferences, including chemical, ionization, physical, and spectral. Chemical interferences occur when other species present chemically react with the species of interest to transform it into a species that is not detected or whose spectral (or mass) signature is different from that of the parent species. Ionization interference occurs when the presence of another species enhances/reduces ionization of the species of interest. Physical interferences are related to changes in the physical characteristics of the sample, such as changes in viscosity, vapor pressure, surface tension/adhesion, etc. Spectral interference occurs when another species present absorbs light at the same wavelengths as the species of interest. Techniques that monitor signal intensity at a specific wavelength rather than by recording the spectrum over a selected region are particularly prone to spectral interference; however, it is often possible to achieve lower detection limits with single-wavelength techniques than with spectrum-recording techniques so the experimenter must decide whether sensitivity or selectivity is more important. Chemical and/or physical separation prior to analysis can substantially reduce interference effects. However, for in situ or screening measurements, purification of the sample may not be feasible.

### 4 EXPERIMENTAL TECHNIQUES

#### 4.1 Infrared Spectroscopy

Vibrational transitions occur in the IR spectral region. Because the location of the peaks depends on the molecular structure, the IR is often referred to as a “fingerprint” region because the pattern of the spectrum can be used to identify the associated species. In the IR region, the NO2 group produces two high-intensity characteristic bands that are associated with the symmetric (νs) and asymmetric (νas) stretching vibrations of the N–O bonds within the NO2 moiety.

In 1960, Pristera et al. reported the IR spectra of 68 explosive ingredients. Based upon their work, characteristic frequencies have been identified; these are summarized in Table 2. Chasan and Norwitz extended this work by recording the IR spectra of 43 of the most common ingredients of primers, tracers, igniters, incendiaries, boosters, and delay compositions. Subsequent investigations have reported the IR spectra of selected explosive materials.

Analysis of an unknown complex explosive solely by IR spectroscopy is generally not recommended because of the uncertainty in interpretation of the spectrum. The certainty with which analysis of the IR spectrum can provide definitive identification of a material greatly increases if prior chemical separation is employed. "Beveridge et al. reported that in a large"
number of analyses of explosive residues, IR spectroscopy detected explosive components in 50% of the tests in contrast to 80% for thin-layer chromatography. Thus IR spectroscopy is a good confirmatory test if sufficient quantity of sample is available.

Wormhoudt et al.\textsuperscript{(38)} have reported their efforts to develop a tunable infrared laser differential absorption spectroscopy (TILDAS) system for in situ identification of the presence of explosives in subsurface soil.\textsuperscript{(39)} In laboratory tests, a 900°C pyrolyzer ring heater was placed a short distance (about 0.25 cm) from the soil surface and the soil heated for periods on the order of minutes. The heat from the pyrolyzer first volatilized and then thermally decomposed the explosive TNT in the laboratory tests. The volatile pyrolysis products (which include NO, NO\textsubscript{2}, and CO\textsubscript{2}) were collected by a ceramic tube located at the center of the ring heater, as shown in Figure 2. The gases then passed through flexible tubing (to permit motion of the pyrolyzer over the soil) and into the multipass detection cell, which is sometimes referred to as a White cell.\textsuperscript{(40)} Spherical mirrors within the multipass cell reflect the laser beam back and forth many times, producing an effective path length for detection of many times the physical length of the cell. Since according to the Beer–Lambert law the absorption magnitude is related to the product of the absorption coefficient, the concentration, and the path length, increasing the path length lowers the minimum detectable concentration. Two tunable lead-salt laser diodes were used for excitation: one excited a NO vibrational transition, and the other excited a NO\textsubscript{2} vibrational transition. The absorptions of the two species as a function of time were monitored. NO and NO\textsubscript{2} had roughly parallel heating time behavior, but the NO signal was much larger than the NO\textsubscript{2} signal. Low NO\textsubscript{2} signal levels were ascribed to rapid secondary reactions of NO\textsubscript{2} produced in the initial bond-breaking steps rather than to a lack of NO\textsubscript{2} formation from the earliest stages of TNT thermal decomposition. The NO\textsubscript{2} disappeared as soon as the heat was removed while some NO was detected for a longer time. Currently the fieldable TILDAS instrument has minimum detectable fractional absorptions in the range 10\textsuperscript{-4} to 10\textsuperscript{-5}. Assuming a minimum absorbance of 10\textsuperscript{-5}, the resulting detection limits for NO, NO\textsubscript{2}, and N\textsubscript{2}O are presented in Table 3. N\textsubscript{2}O is not a major product of TNT decomposition, but it is for decomposition of nitramines (such as HMX and RDX). Therefore, monitoring of N\textsubscript{2}O would allow nitramines to be distinguished from nitroaromatics.

Riris et al.\textsuperscript{(41)} have demonstrated detection of explosives using catalysts to facilitate decomposition of explosives and subsequent detection using a frequency modulation technique. The frequency modulation technique consists of rapidly changing the laser wavelength between two chosen wavelengths: one of which corresponds to a transition of a species of interest and the other is a nearby wavelength that does not excite that species. By comparing the on-resonance and off-resonance signals, the concentration of that species can be deduced. A schematic of their apparatus is presented in Figure 3. Three different lead-salt laser diodes were used: one was tuned to 4.57 \textmu m where N\textsubscript{2}O absorbs, another to 5.25 \textmu m where NO absorbs, and the third to 6.24 \textmu m where NO\textsubscript{2} absorbs. The three laser beams were combined and sent through the sample cell and then through a calibration cell that was filled with known quantities of N\textsubscript{2}O, NO, and NO\textsubscript{2}. Dichroic beam splitters were used to separate the laser beams exiting the cells and to direct the light onto IR detectors that were dedicated to each species. In this manner, the concentrations of N\textsubscript{2}O, NO, and NO\textsubscript{2} were simultaneously determined. For their prototype, their LOD for RDX was 5–10 pg, although the theoretical LOD was 0.005 pg RDX. They anticipate that in a fieldable system, it will be possible to reduce the achievable LOD by an order of magnitude.

4.2 Raman Spectroscopy

In simplistic terms, the Raman effect signal results from an inelastic collision between a photon and a molecule.\(^{42,43}\) A Raman transition is separated from the excitation laser wavelength by an energy difference (\(\Delta \nu\) or \(\Delta \omega\), usually measured in units of \(\text{cm}^{-1}\)) that corresponds to a vibrational energy difference in the molecule’s ground electronic state. As shown in Figure 4, those Raman transitions that are at lower energy than the excitation laser are said to be Stokes transitions and those that are at higher energy are termed anti-Stokes transitions. Both types of transitions can simultaneously occur in a single Raman spectrum. Since the intensities of anti-Stokes transitions is much, much weaker than those of Stokes transitions, the Stokes transitions are generally used for analytical characterization.

Most of the Raman spectroscopy research directed toward detection of explosives has concentrated on the use of two approaches: Fourier transform Raman spectroscopy (FTRS) and Raman laser microprobe spectroscopy. Figure 5 shows a schematic of a FTRS apparatus. A rejection filter is placed between the laser and the beam separator to insure that only one wavelength of light is used to excite the sample; this is done to filter out stray flashlamp light from neodymium : yttrium aluminum garnet (Nd: YAG) laser beams or other lines from argon ion (Ar\(^+\)) laser beams. The laser beam irradiates the sample and the reflected light (which includes the Raman signal) is directed into a scanning interferometer. The resulting interferogram is detected and recorded on a computer. Fourier transforming the interferogram yields the entire Raman spectrum. Since the entire spectrum is recorded simultaneously, this technique requires a much shorter data acquisition time than those that require scanning of a spectrometer. Typically 100–500 scans are co-added to improve the signal-to-noise ratio (S/N).

A schematic diagram of a Raman laser microprobe apparatus is presented in Figure 6. Many researchers have devised different Raman laser microprobe configurations.\(^{45}\) In the variation developed for explosives by Hayward et al.,\(^{46}\) a fiber optic cable was utilized to transport the light from the laser to the microprobe head. Inside the microprobe head, the laser beam was filtered to remove any unwanted laser wavelengths and then directed onto a microscope objective lens that focused the light to a small diameter, typically on the sample.
order of tens of micrometers. The Raman signal passed back through the microscope lens and then through a holographic notch filter that transmitted the Raman-shifted signal, but not the laser wavelength. The signal was focused into a fiber optic cable for delivery to a scanning spectrometer for detection by a multichannel charge-coupled device (CCD) detector. The advantage of the Raman laser microprobe technique is that by increasing the laser flux by focusing the laser beam to a small diameter, it is possible to detect lower concentrations than is possible with the FTRS technique. One of the limitations of the Raman laser microprobe technique is the necessity of precisely positioning the laser beam. Most reports have not dealt with the problem of identifying the exact location of the sample; sample location is one of the primary challenges facing those who perform forensic analyses of bomb explosion sites since minuscule explosive residuals may be present on objects hurled significant distances by the force of the explosion. Hayward et al. utilized an XYZ stage to translate the sample while monitoring the Raman signal in the 400–1300 cm\(^{-1}\) range and more thoroughly investigating those regions exhibiting a strong Raman peak near 880 cm\(^{-1}\) from RDX or PETN.

Table 4 compares the LODs achieved using macrosampling and microsampling (Raman laser microprobe) as determined by Carver et al.\(^{(47)}\) By moving a mirror, they could change from microprobe to macrosampling. Using the microprobe, slightly lower LODs could be obtained than with macrosampling (FTRS): this is due to the opposing contributions from more efficient signal collection by the microprobe and the smaller sample area for microprobes (typically a few tenths of a square millimeter for microprobes vs a few square millimeters for macrosampling).

Factors affecting the detection limits include: sample purity; sample thermal history; backscattered radiation from the substrate; the Raman spectrum of the substrate; fluorescence of substrate; packing; excitation wavelength; fluorescence of analyte; laser power; detector sensitivity; and laser beam spot size on the sample. Backscattered radiation is much more pronounced from silica gel than from activated charcoal or glass.\(^{(47)}\) However, activated charcoal produces its own Raman signals, which may interfere with those of explosive analytes.\(^{(48)}\) Carver et al.\(^{(47)}\) believe that glass is the ideal support material for Raman detection of explosives because it has a weak Raman spectrum and gives only minimal backscatter. Lewis et al.\(^{(49)}\) have reported both solid and liquid explosives could be successfully analyzed in common glass and plastic containers when near-infrared (NIR) excitation is used.

Whether the sample is loosely packed or tightly compressed can have a strong effect on the spectral S/N.\(^{(49)}\) Compressing the solid sample increased the rate of heat transfer from the sample to the container and hence reduced the effects of laser heating; for the loosely packed particles, the effects of laser heating of the sample were manifested by thermal emission above 2500 cm\(^{-1}\) and a significant baseline offset.

The effect of laser excitation wavelength on the Raman signal is also important.\(^{(49)}\) The Raman intensity increases with increasing laser excitation frequency (and hence

</table>
decreasing laser excitation wavelength) since the Raman intensity is related to the scattered frequency \( \nu \) as shown in Equation (1):\(^{43}\)

\[
I_{v,J} = \left( \frac{2\pi}{c} \right)^4 \nu^4 I_L \frac{N_{v,J}}{J+1} (\omega)^2, \Omega \ell
\]

(1)

where \( I_{v,J} \) is the Raman intensity, \( c \) is the speed of light, \( \nu \) is the frequency of the Raman scattered radiation, \( I_L \) is the intensity of the incident radiation, \( N_{v,J} \) is the population in vibrational state \( \nu \) and rotational state \( J \), \( \alpha \) is the polarizability matrix element, \( \Omega \) is the solid angle, and \( \ell \) is the scattering length. Thus the shorter the excitation wavelength, the larger the Raman intensity. Since fluorescence is typically orders of magnitude more intense than the Raman signal,\(^{42,43}\) it is essential to minimize fluorescence in order to obtain quantitatively reliable Raman spectra. Because fluorescence typically increases with decreasing excitation wavelength, the gain in Raman intensity is counterbalanced and often overpowered by an increase in fluorescence with decreasing wavelength. Thus, using longer excitation wavelengths decreases fluorescent interference, but increases data acquisition time: in order to obtain Raman spectra of 3,3’-diamino-2,2’,4,4,6,6’-hexanitrophenyl (DIPAM) of approximately the same quality, Lewis et al.\(^{46}\) needed 1 s integration time at 632.8 nm with 10 mW laser power, 10 s integration time at 785 nm with 5 mW laser power, and for a FTRS system at 1064 nm, 10 min integration time with 100 mW laser power. They\(^{49}\) tested 32 pure or composite explosives and found that 23 of the samples could be adequately analyzed using all three excitation wavelengths that they investigated (632.8, 785, and 1064 nm); however, they concluded that the optimum laser excitation wavelength for analysis of explosives is probably in the range between 785 nm and 1064 nm.

Thermal and/or laser heating of the sample can thermally decompose explosive samples. McNesby et al.\(^{50}\) noted that TNT can be decomposed due to exposure to laser radiation (and hence laser heating); for TNT they had to use lower laser powers to prevent the sample from combusting. They\(^{51}\) also noted that thermal decomposition begins below the melting point of RDX and RDX-based propellants. In addition to thermal decomposition, laser heating may result in sample melting or sample vaporization. Based on similar chemistry, similar thermal effects can be expected for other explosives. Hodges and Akhavan\(^{52}\) encountered problems when black or darkly colored samples were investigated: these samples efficiently absorbed the IR radiation, leading to sample heating and eventual burning. They\(^{52}\) investigated a variety of techniques in an effort to overcome this difficulty. These efforts included defocusing the laser beam, reducing the incident laser power, accumulating single scans, and collecting data at lower resolution (and hence with shorter data acquisition times). None of these efforts resulted in success. McNesby et al.\(^{51}\) report that laser sample heating is more important for 1064-nm excitation than for 514-nm excitation. Moreover, laser sample heating becomes increasing significant as the bulk sample temperature is raised.

McNesby et al.\(^{50,51}\) studied the effects of bulk and laser heating on the Raman spectrum of solid explosive samples. In general as the temperature of a sample increased, the intensity of Raman transitions decreased and their peak frequencies moved to lower energy. There was also a noticeable variation in relative Raman peak intensity with increasing temperature, which has been interpreted as an indication of an increase in the lattice spacing and hence a loss of order within the crystal. They\(^{51}\) believe that in order of decreasing importance, for their experimental set-up, the factors contributing to the decrease in Raman signal intensity with increasing sample temperature are laser sample heating, density changes, population changes, and changes in refractive index and reflectivity. They emphasize the importance of minimizing the intensity of the excitation radiation.

Recently Lewis et al.\(^{53,54}\) have made a major advance in developing Raman spectroscopy as an automated analytical technique for identification of explosives. They recorded the FTRS spectrum of 32 nitro-containing explosive materials and have obtained a classification scheme based upon the symmetric and asymmetric \( \text{NO}_2 \) stretching vibration transitions, which is graphically presented in Figure 7. By the use of these two frequencies, it is possible to at least identify a cluster of explosive materials that will include the analyte. Using this classification scheme as a foundation, they have studied various means of computer-based, unsupervised pattern recognition involving neural networks, fuzzy logic, and statistical models. The use of computer-based data analysis will significantly reduce the time required for characterization of a sample and will ultimately permit the development of a commercial Raman system for explosives analysis that does not require a highly trained Raman spectroscopist for rapid and successful analysis.

Kneipp et al.\(^{55}\) have reported NIR surface-enhanced Raman scattering (SERS) of TNT on colloidal gold and silver. Addition of TNT to colloidal silver produced a strong coagulation with the resulting particles too big to produce a large signal enhancement. In contrast to silver, the SERS spectrum of TNT absorbed on gold exhibited significant signal enhancement, enabling concentrations down to \( 10^{-7} \) M TNT (about 1 pg of TNT) to be detected. Moreover, the SERS spectrum of TNT on gold displayed many Raman bands strongly related to the spectrum of “free” TNT molecules, while TNT on silver displayed only a single Raman transition. This work demonstrates
Figure 7 Plot of frequency of asymmetric NO$_2$ stretching transition vs frequency of symmetric NO$_2$ stretching transition for nitro-containing explosives. Dashed lines indicate the range of each corresponding explosive class: nitro-aromatic ( ), nitrate ester ( ), and nitramine ( ). The classes are nitro-aromatic ( ), nitrate ester ( ), nitramine ( ), and exceptional ( ) explosives. This classification scheme was devised by Lewis et al. (Reproduced by permission of Society for Applied Spectroscopy.)

the feasibility of using SERS for ultratrace analysis of explosive materials.

McNesby and Coffey have recently demonstrated the use of Raman spectroscopy for determination of the impact sensitivities of explosives (such as HMX, PETN, RDX, TNT, and 1,3,5-triamino-2,4,6-trinitrobenzene (TATB)).

4.3 Photoacoustic Spectroscopy

PAS, which is also referred to as optoacoustic spectroscopy, is performed by irradiating a sample cell with a tunable pulsed-light source, typically a laser, and monitoring the resulting pressure changes using a microphone. If the wavelength of the tunable light source is scanned, a PAS spectrum is obtained that is analogous to an absorption spectrum. A schematic of a typical PAS system is shown in Figure 8.

Using CO and CO$_2$ lasers in the 6-, 9-, and 11-µm regions, Claspy et al. have reported PAS detection of vapors of NG, EGDN, and DNT. Their detection limits are presented in Table 5. In addition to investigating the optoacoustic spectroscopy of these explosives, they also investigated the PAS of possible spectral interferents (NO, NO$_2$, CH$_4$, C$_2$H$_6$, and H$_2$O). In the 6-µm region, water vapor, NO$_2$, and NO give rise to spectral interferents of varying degrees of severity, depending on the explosive involved; of these, water vapor presented the most difficulty. The water was present in the air and was also entrained in the NG and EGDN explosives. In the 9- and 11-µm regions, none of the possible interferents absorbed laser radiation. Consequently, Claspy et al. recommended that PAS systems designed to detect explosives operate in the 9- to 10-µm or 11- to 12-µm regions.

Crane extended the work of Claspy et al. by measuring the PAS absorption coefficients of EGDN, NG, and DNT for about 77 CO$_2$ laser transitions in the 9.6-µm and 10.6-µm regions. The minimum detectable concentrations reported are significantly lower than those reported by Claspy et al. (Table 5): 8.26, 0.23, and 0.50 ppb by weight for EGDN, NG, and DNT respectively. Crane noted that the tendency of explosives to adhere to metal surfaces (such as the microphone) made determination of detection limits difficult. In contrast to the report by Claspy et al., Crane observed no detectable saturation with laser power at power levels 40 times those used by Claspy et al. Since Claspy et al. did not provide a sufficiently detailed description of their system, Crane was unable to offer an explanation for this discrepancy.

Williamson et al.\(^{(60)}\) have used ultraviolet (UV) laser radiation near 226 nm and obtained PAS LODs of 1.2, 2.8, and 4.9 ppm for detection of NO in Ar, N\(_2\), and air respectively. Since NO is generated by the decomposition of many explosive materials, it may be possible to use detection of NO as a screening method for detection of explosive materials.

Recently Hasue et al.\(^{(61)}\) have reported the PAS spectrum of 18 energetic material powders in the 400- to 1600-nm region. Tunable radiation in this spectral region was obtained by using a monochromator as a tunable bandpass filter for a 500-W xenon lamp in the 400 to 800-nm region and a 300-W halogen lamp in the 800 to 1600-nm region. As with the IR laser work described in section 4.1, pulsed radiation was achieved by employing an optical chopper to alternatively transmit and block the light. Figure 9 presents the PAS spectrum of TNT. Hasue et al. found that, in general, the energetic materials studied exhibit PAS peaks in the 600 to 800-nm and 1400 to 1600-nm regions. Furthermore, they found that the energy required to initiate explosives using a ruby laser (694 nm) was correlated with the PAS signal intensities. Hasue et al. did not report detection limits, but they did report PAS signal intensities from which relative detection efficiencies can be inferred.

The current status of PAS detection of explosives is that the feasibility of detecting explosives at low concentrations has been established. Using vapor-phase samples, it is possible to achieve sub-ppb detection. However to date, it has not been demonstrated that different explosives can be distinguished using PAS because at the resolution reported, the spectra are not sufficiently distinct from other explosive materials or from other organic compounds. Moreover, vapor-phase PAS detection of explosives is subject to the experimental difficulties that elevated temperatures are required to obtain appreciable vapor and the pronounced tendency of explosives to adhere to surfaces, especially metal surfaces; the latter places restrictions on the materials used in the apparatus and also means that care must be taken to avoid memory effects.

### 4.4 Ultraviolet/Visible Absorption Spectroscopy

The UV spectrum of nitro compounds is dominated by an \(n \rightarrow \pi^*\) electronic transition primarily associated with the nitro group. Because of their low vapor pressures and pronounced tendency to decompose at elevated temperatures, the available UV spectra of nitro compounds have primarily been recorded either in solution or in the solid phase; gas-phase spectra are rare.\(^{(62,63)}\) The UV electronic transitions of nitro compounds appear as broad, structureless transitions; this is due in part to the broadening induced by the medium and in part by a tendency toward photofragmentation (PF) (and hence broadening due to the Heisenberg Uncertainty Principle). Aliphatic nitro compounds exhibit very low intensity absorption bands in the 260- to 270-nm region.\(^{(11,64)}\) Aromatic nitro compounds reveal sharp, intense absorption bands in the 210- to 280-nm region.\(^{(65-67)}\) Owing to the influence of a large number of nitro groups on the aromatic ring, the absorption maximum can be shifted and the intensity altered. For the case of nitric esters, an extremely weak absorption band at about 265 nm arises because of the nitroxy group.\(^{(66,68)}\) Nitramines in solution exhibit a broad UV absorption between 225 and 240 nm.\(^{(67-71)}\)

Changing the solvent changes the position of the maximum and may affect the intensity. Changing from polar to nonpolar solvents causes a shift to shorter wavelengths for aromatic nitro compounds\(^{(72)}\) and a shift to longer wavelengths for aliphatic nitro compounds.\(^{(73)}\)

Schroeder et al.\(^{(66)}\) have published the UV/VIS absorption spectra of 135 explosive or explosive-related compounds in ethanol solution; their paper includes the molecular absorption coefficients of peak maxima. Figure 10 presents the UV absorption spectra of selected nitramines and nitroalkylenes in ethanol solution. Recently solid-state UV/VIS spectra of such explosive compounds as PETN, RDX, HMX, and 2,2',4,4',6,6'-hexanitrostilbene (HNS) have been published.\(^{(71,74)}\) In comparison with spectra recorded in acetonitrile solution, the solid-state spectra generally have absorption maxima shifted to longer wavelengths.

Because the UV absorptions of nitro compounds in solution and in the solid phase are broad, weak, and generally structureless, UV/VIS absorption spectroscopy cannot provide definitive identification of specific nitro compounds without chemical separation. However, if a separation technique (such as high-performance liquid chromatography (HPLC)) is used, minimum detection limits of 0.03 to 0.21 \(\mu g L^{-1}\) can be achieved.\(^{(67)}\)
ENVIRONMENT: TRACE GAS MONITORING

Figure 10 UV absorption spectra of selected explosive compounds in ethanol solution: 12, HMX; 13, 20, 2-nitrotoluene; 21, 4-nitrotoluene; 22, 2,4-DNT; 23, 2,4-dinitro-1-ethylbenzene; and 24, TNT. (Reproduced by permission of the American Chemical Society.)

Because of the very low vapor pressures of the common explosive materials, application of UV/VIS absorption spectroscopy to vapor-phase samples is not practical using current commercial UV/VIS spectrometer systems; however, it may be feasible using cavity ringdown spectroscopy.

4.5 Laser-induced Fluorescence

LIF is simply the optical emission from molecules that have been excited to higher energy levels by absorption of laser radiation. The main advantage of using fluorescence detection compared to absorption measurements is the greater sensitivity achieved because the fluorescence signal has a very low background. LIF has been used to study the electronic structure of molecules and to make quantitative measurements of concentrations. Analytical applications of LIF include monitoring gas-phase concentrations in the atmosphere, flames, and plasmas; and remote sensing using light detection.

LIF for the detection of explosives is usually combined with PF in order to photodissociate a target molecule and subsequently detect the fluorescence of the generated photofragments. This NO$_2$ functional group is responsible for the weak and structureless UV absorption of TNT near 226 nm. The 226-nm laser radiation photodissociates TNT and produces NO$_2$ in the ground electronic state ($X^2A_1$). The NO$_2$ generated then absorbs a 226-nm photon and undergoes a transition to the $2^2B_2$ electronic state. The $2^2B_2$ state predissociates rapidly to produce NO in the ground vibrational state of the ground electronic state ($X^2A_1$) and atomic oxygen. The ground state NO then absorbs another 226-nm photon to undergo a resonant transition ($A^2E^+\nu'=0 \rightarrow X^2\Pi \nu''=n$, where $n=0,1,2,3,\ldots$) fluorescence. PF and predissociation are achieved with the same UV laser frequency. This allows for a simple experimental set-up for detecting nitro compounds. The intensity of the NO fluorescence is related to the concentration of TNT in the sample.

Figure 11 shows a schematic of a PF/LIF experimental system used to detect TNT. A UV laser power of 2 $\mu$J at 226 nm is sufficient for the PF and to induce fluorescence. A photomultiplier tube (PMT) detects the
PF/LIF signal that can be averaged and recorded on a digital oscilloscope. The dye laser wavelength can also be scanned to collect PF/LIF spectra. These spectra can be used to identify the wavelength of the highest intensity LIF signal.

This application of using PF/LIF to detect TNT has also included studies of effects on the PF/LIF signal. Increasing the sample temperature increases the PF/LIF signal intensity, but also produces physical and chemical changes to the sample. This is also true for reheating the samples and increasing the heating time. Increasing sample concentration and laser power also increases the intensity of the PF/LIF signals. The PF/LIF signals show a large intensity increase and then a long decay. Analysis of the decay identifies characteristic decay lifetimes and further characterizes the PF/LIF signals. Studies have also been performed to identify the effects of water, fertilizer, and other common soil additives. Water quenches the fluorescence and must be boiled or removed from the sample. Fertilizer shows similar signals to small concentrations of TNT, but has little effect when added to TNT samples, at least at the concentrations studied to date.

A common error in measurements with LIF is the variation in collisional quenching. This process competes with fluorescence as a method for excited-state molecules to become de-excited. The rate of collisional de-excitation determines the fluorescence yield (fraction of fluorescing molecules/atoms to the total number excited) and is dependent on the mixture of molecular/atomic species, and their densities and temperature. Fluorescence from other species can also compete and lead to errors in measurements. Modern lasers provide sufficient power to saturate transitions; this results in the fluorescence no longer being linearly related to the laser energy. Under these saturated conditions, the fluorescence becomes insensitive to quenching variations (since stimulated emission dominates quenching as a loss mechanism), and thus some techniques employ this method.

The technique of LIF has been applied to several nitro compounds, including TNT, nitrobenzene, and dinitrobenzene. The sensitivity of PF/LIF is very dependent upon the spectroscopic characteristics of the target molecule, the detected fragment and the laser system used for the measurement. The reported LODs for nitro compounds are presented in Table 6. Since the technique has a strong dependence on the laser radiation characteristics, the applications and sensitivity of PF/LIF will increase with improvement of laser systems.

In addition to PF/LIF, other fluorescence-based techniques have been used to detect explosive materials. Jian and Seitz have reported optical detection of nitro compounds via fluorescence quenching. When aqueous nitro compounds were passed through a fluorophore-containing membrane, fluorophore fluorescence intensity was reduced. The response is generic to nitro compounds and cannot be used to identify which compound is involved. Nitrogen purging prior to measurement eliminated interference from oxygen and enhanced sensitivity. LODs are about 2 mg L\(^{-1}\) for DNT and TNT and 10 mg L\(^{-1}\) for RDX; it is desirable to have even lower LODs. When combined with fiber optic excitation and detection, the membrane can be used for remote in situ screening of groundwater for contamination by explosive materials. Crowson et al. have investigated detection of explosives by gas-phase chemiluminescence. They reported that when vapors from a variety of explosive compounds were thermally decomposed, a blue-green chemiluminescent emission was observed. Simple alkyl nitrates are more thermally stable and hence can be detected at lower concentrations than RDX or PETN. No signal was observed for TNT. For pure vapors, the LODs approached the limit of accurate pressure measurements. The use of carrier gases significantly decreased the achievable LODs: significant improvement occurred with nitrogen and even greater improvement with helium. The authors believed that in the absence of carrier gases, the explosives tended to either be retained within or decomposed within the heated injector. The LOD under static conditions for isopropyl nitrate was 0.013 Pa in 1.3 \(\times\) 10\(^4\) Pa of helium (1 ppm). Like the membrane fluorescence quenching technique described above, the chemiluminescence technique does not identify which explosive material is present, but can be used for screening.

4.6 Ionization-based Detection Techniques

4.6.1 Ion Mobility Spectrometry

Mass spectrometry (MS) is a very powerful and sensitive technique for detection and characterization of a wide array of species. IMS\(^{91-93}\) is a modified form of time-of-flight (TOF) MS which operates at atmospheric pressure. IMS is neither a laser- nor an optical-based detection technique, but it is included for completeness. The principle of operation of IMS can easily be understood from Figure 13. An IMS analyzer consists of a sample ionizer, reaction region, shutter grid, drift region, aperture grid, and a signal collector. The vapor sample is introduced into the IMS cell with the help of a carrier gas, such as air, CO\(_2\), argon, helium, or nitrogen. The sample constituents are ionized along with the carrier gas. Ionization is usually accomplished by bombarding the gas with electrons produced by the radioactive decay of \(^{63}\)Ni, but ionization can also be accomplished by a laser or by an UV/vacuum UV light source. The ionized species travel across the reaction region under the influence of an electric field and reach the shutter grid. The shutter grid consists of sets of thin wires with a voltage bias between them, establishing a localized electric field perpendicular to the direction of flow. This electric field controls entrance of ions into the drift region. When the bias voltage is applied to the shutter grid, the ions are attracted to the grid and lose their charge. When the voltage across the shutter grid is momentarily turned off, ions are transmitted into the drift region.

In the drift region, ions with different mass, charge, and shape travel with different velocities for a given applied constant electric field. The motion of ions through the drift region is hindered by a countercurrent flow of drift gas. The drift velocity of ions defines the ion mobility. Thus the mobility of different ions are different. Ions with smaller mass travel with higher velocity than those with larger mass and reach the collector in shorter time. After the drift region, the ions pass through an aperture grid which prevents an electrical signal being induced on the collector before the ion clouds reach the collector. The ions accumulated on the collector produce an electrical signal that is measured by an electrometer. The different mass ion clouds arrive at the collector at different times. The resulting plot of collector current versus time is referred to as the mass spectrum of the sample. This spectrum is recorded by a data acquisition and analysis system.

The arrival time at the collector depends on the electric field strength in the drift region. Typically ions are introduced into the drift region by the shutter grid every 20–40 ms. The shutter grid is open for typically about 0–0.4 ms. The shutter grid is used to synchronize the signal collection of IMS spectra. To improve S/N, several hundred scans may be averaged. The IMS spectra of both reactants and products are recorded. The recorded spectrum is compared with the library of reference data available on different ions. These data are used to identify the species. The signal intensity at a particular time corresponds to the concentration of the associated species.

As an analytical technique, IMS has several advantages.\(^{91}\) First for many compounds, the detection limits are in the picogram or sub-ppb range. Second, IMS has selectivity based on ion mass, electric field strength, and electric field polarity; these allow specificity of

![Figure 13](image-url) Schematic of IMS apparatus.\(^{95}\) (Reproduced by permission from *Sensors* (www.sensorsmag.com), April, 1994, Helmers Publishing, Inc., Copyright 1994.)
LASER- AND OPTICAL-BASED TECHNIQUES FOR THE DETECTION OF EXPLOSIVES

15
detection even in the presence of matrix interferents. Third, the system can be easily automated to perform suitable sampling, calibration, and data analysis. Fourth, IMS analysis is rapid, typically under a minute for data acquisition and processing. All techniques have limits/weaknesses; those of IMS include (1) the response varies with background gas composition (consequently peak intensity alone is not sufficient for quantitative analysis), and (2) for some compounds, IMS has a limited linear range (in some cases as small as an order of magnitude although some compounds have linear ranges of up to five orders of magnitude).

IMS detection of explosive materials has been reported since the early 1970s. In 1978, Spangler and Lawless investigated the processes of negative ion formation in nitrotoluene compounds. They reported a practical detection limit of 10 ppt (mol mol\(^{-1}\)) for TNT in air. In general, negative ionization provides a high degree of selectivity because only highly electronegative compounds, such as explosives, are ionized. Addition of \(\mathrm{Cl}^-, \mathrm{Br}^-, \mathrm{I}^-\) ions leads to an enhanced ability to detect NO\(_3^-\) from fragmentation of explosive materials. Qualitative identification of explosives by IMS has been reported by various researchers with a variety of very low detection limits. According to Cohen et al., rapid explosive vapor detection by IMS is feasible down to \(10^{-14}\) parts by volume in air; other researchers report that laboratory detection limit is as low as 200 pg for common explosives (such as NG, PETN, RDX, and TNT). IMS quantitative detection of TNT has a linear response between 300 and 5000 pg of TNT with a precision of 0.2–1.0%. Thus the concentrations at which explosive materials can be identified by IMS are significantly lower than concentrations for which quantitative determinations can be made. Recently, Eiceman et al. have compared the results of an IMS with those of the NIST gravimetric method for TNT vapor from a vapor generator at 79 °C and obtained exact agreement within experimental uncertainty.

The ability of IMS to detect explosives in practical situations has also been investigated. NG, PETN, and RDX have been detected by IMS in post-blast analysis of the remains of pipe bombs, steel plates, suitcases, and cassette/radios. IMS analysis of post-blast residues requires that the sample be dissolved in a solvent for injection into the IMS spectrometer. Solvation of the sample permits purification of the compounds by chemical and/or physical methods, enabling IMS detection of sub-nanogram quantities of explosives in post-blast residues. Handling of commercial and military explosives leaves residuals on hands that can subsequently be transferred to other surfaces. IMS has detected RDX on hands and various car parts following handling of the explosive; eight consecutive hand washings with soap and water were required before IMS could no longer detect the RDX.

TNT vapors can easily be detected by IMS, but the vapors of RDX and of PETN cannot be readily detected without the use of a preconcentrator. The vapor pressure of RDX is about four orders of magnitude less than that of TNT, making detection of RDX more difficult than TNT. Field samples are typically collected by vacuuming a pre-selected surface area. IMS detection of explosives using laser desorption was demonstrated in 1987.

In order to be a viable field instrument, IMS must have an automated data analysis system capable of determining whether or not a peak has been detected. Currently research efforts are underway to combine IMS with real-time data processing using neural network techniques.

4.6.2 Resonance-enhanced Multiphoton Ionization Spectroscopy

MS combined with various preparation techniques has been very extensively utilized for identification and characterization of explosive materials. A review of the extensive MS literature on detection of explosives is beyond the scope of this article. We will instead restrict ourselves to laser- and optical-based ionization techniques that have been combined with mass spectrometric detection, specifically REMPI spectrometry, which is sometimes also referred to as resonant ionization mass spectrometry (RIMS). Generally RIMS refers to detection of atoms and REMPI to detection of molecules. A related technique, photofragmentation/photoionization (PF/PFI) spectroscopy, uses charged plates to collect the ion signal rather than a TOF mass spectrometer as REMPI does. For the purposes of this review article, we will group REMPI, RIMS, and PF/PFI together.

A schematic of a typical REMPI apparatus is presented in Figure 14. A gas-phase sample is introduced into the apparatus, typically in the form of a molecular beam. A high-power, pulsed laser is used to induce multiphoton absorption, resulting in fragmentation and ionization. The resulting ions are detected in a manner similar to that for IMS. With regard to detection, the primary difference between IMS and REMPI is that an IMS experiment uses a carrier gas and a REMPI experiment is performed under vacuum. As with IMS, entry of the ions into the drift region is controlled by grids at high potential, and the mass of the ions is related to the time the ions require to move from the ion formation region to the detector. Again the plot of detector signal vs time is referred to as a mass spectrum.

Marshall et al. have demonstrated that PF of nitroaromatic compounds occurs by predissociation,
releasing an NO2 fragment, which subsequently pre-
dissociates to form NO. The NO generated can sub-
sequently undergo multiphoton ionization to produce
NO+, which appears prominently in the mass spectrum.
Different nitroaromatics can be distinguished from each
other by the wavelength dependence of the NO+ ion
formation,\(^\text{112}\) provided that enough sample is available.
Moreover, NO+ ion formed from NO or NO2 can be
distinguished from NO+ formed from nitroaromatic com-
pounds in vacuum by the wavelength dependence of the
NO+ ion formation.\(^\text{112}\)

Multiphoton fragmentation and ionization can occur by
two distinct mechanisms.\(^\text{107–110}\) First, molecules absorb
a number of photons, exciting them to a dissociative state
below the ionization limit. If the laser pulse duration is
much shorter than the lifetime of the dissociative state,
then the up pumping rate may be so high that ionization
occurs before dissociation. The ions may absorb additional photons before fragmenting. This
process is ionization followed by dissociation (DI) or
ladder climbing. However, if the laser pulse duration is
longer than the dissociative state lifetime, then the
molecule dissociates forming neutral fragments. If the
laser intensity is sufficiently high, these fragments may
absorb additional photons to further fragment or to
ionize. This process is dissociation followed by ionization
(DI) or ladder switching. For analytical purposes, DI
fragmentation is not very useful because neither parent
nor structurally distinctive ions are formed. Thermally
labile molecules, which includes many nitro compounds,
fragment primarily by the DI route while many molecules,
such as aromatics, fragment by the ID route alone. Clark
et al.\(^\text{113,114}\) have reported REMPI detection of C, H, and
O atoms following photodissociation of nitrobenzene.
Recently Ledingham et al.\(^\text{115}\) have shown that use of
femtosecond lasers enhances the ability to identify the
parent ion by promoting the ID route. This is important
since identification of parent species can be difficult if
the original molecule is extensively fragmented by the
excitation process or if only a few fragment moieties are
ionized. For example, only the NO+ ion is present in
the REMPI mass spectrum of nitrate esters using
nanosecond excitation.\(^\text{116}\) Among the nitro compounds
studied to date by femtosecond REMPI are NO2,\(^\text{117}\)
nitromethane,\(^\text{118}\) nitrobenzene,\(^\text{119}\) and nitrotoluene
isomers.\(^\text{119}\)

Quantitative REMPI determinations of nitro
compounds have been reported in a variety of papers.\(^\text{82,112,116,120–125}\) The lowest detection limits are
presented in Table 7. Several researchers have noted that
the detection limits are wavelength depen-
dent.\(^\text{112,120,123,126}\) In general, the shorter the excita-
tion wavelength, the lower the detection limit. Recently
Elwood and Simeonsson\(^\text{126}\) have demonstrated that sub-
stantially lower LOD for NO can be achieved using
215 nm + 355 nm excitation rather than with single-color
excitation.

As a detection technique for explosives, REMPI has the
advantage of having very low detection limits, typically
10–100 pg with nanosecond excitation. To date, REMPI
analysis of explosive materials has only occurred in
academic rather than forensic laboratories.

### 5 ENVIRONMENTAL APPLICATIONS

Explosives are dangerous not only owing to their
explosive nature, but because they also present a
potential health hazard since they are toxic.\(^\text{15}\) There
are contaminated sites near military test ranges and
ammunition plants all over the world. Unexploded or
partially exploded ordinance buried in the ground slowly
releases the explosive into the soil. These explosive
compounds slowly migrate deeper and deeper and, in
time, reach groundwater level. These toxic compounds
can subsequently be ingested by people from drinking
water. Contamination is difficult to clean up once the

toxic substance has reached groundwater level. Thus, detection of explosive materials in soil before it reaches groundwater is important.

Various techniques for monitoring explosives in soil and groundwater have been evaluated. A mobile cone penetrometer system (Site Characterization and Analysis Penetrometer System (SCAPS))\textsuperscript{(39,127)} that can position sensors at selected distances below the surface in order to measure the concentration of explosives or other pollutants (such as petroleum, oils and lubricants (POLs), volatile organic compounds, metals, and radioactive contaminants) as a function of depth has been developed and field tested. In general, the sensors provide rapid screening information – for example, a sensor might quickly indicate that explosives are present and what their concentration is, but might not indicate which explosive is involved. A precise chemical analysis can then be performed by sending a sample to an analytical laboratory. By combining concentration vs depth information for a variety of different surface locations with high-power computers, three-dimensional maps of subsurface pollution distributions can be obtained. These three-dimensional maps are critical to insure that all contaminated areas are cleaned up while effort and funds are not expended on uncontaminated areas.

The SCAPS was initially developed during the late 1980s. Figure 15 shows a typical cone penetrometer system for environmental site characterization and monitoring.\textsuperscript{(39,127)} The SCAPS system includes a custom-engineered, 20-ton truck capable of hydraulically pushing an instrumented probe down to depths of up to 50 m. The truck is separated into two parts: one contains the penetrometer push/pull system, and the other contains most of the measurement equipment. Optical, electrochemical, and chemical cone penetrometer sensors have been developed and evaluated. Laser-based sensors are being developed in the laboratory which can be incorporated into a SCAPS probe.

Previously in this article, we have described the detection of explosive pyrolysis products from soil detected by TILDAS\textsuperscript{(38)} (Figure 2 and Table 3) and the detection of TNT in soil by PF/LIF spectroscopy\textsuperscript{(84–86)} (Figure 12 and Table 6). In the following paragraphs, some of the applications of SCAPS for explosive detection for environmental application along with analytical methods will be discussed. Traditional methods are also presented for the sake of completeness.

Jenkins et al.\textsuperscript{(128)} have summarized the analytical methods currently used for characterization of explosive contaminated sites at US Army installations. These include on-site field screening and off-site laboratory analysis. The laboratory techniques are those in general use in forensic laboratories.\textsuperscript{(1,12)} In the laboratory, explosives are extracted from soil and water samples prior to analysis. In general, Soxhlet extraction and ultrasonic methods recovered similar amounts of explosives from samples. They recovered more than mechanical shaking does, particularly when analyte concentration is low. Analysis of water samples with low explosives concentration is often performed after pre-concentration. This is achieved by solvent extraction or solid-phase extraction. The high polarity of the aromatics limits the types of solid phases that can be used. Reversed-phase HPLC is used most of the time to analyze the explosives after extraction and pre-concentration.

In an accompanying paper, Jenkins et al.\textsuperscript{(129)} have reviewed colorimetric methods used for field screening. The field screening results were compared with standard laboratory techniques and were found to be in reasonably good agreement. In colorimetry, explosive materials react with appropriate chemicals and the mixture undergoes a color change. The intensity of the color (as measured by absorption spectroscopy) gives the concentration of the explosive. The LODs of different colorimetric reagents for various explosives are typically in the range 0.1 to 0.3 absorptivity units mg$^{-1}$L$^{-1}$ for polynitroaromatics and 0.004 to 0.16 absorptivity units mg$^{-1}$L$^{-1}$ for nitramines and nitrate esters.

Levsen et al.\textsuperscript{(130)} have described the detection of explosives and related compounds in aqueous samples from former ammunition production sites in Germany. They have presented the analysis of the sample using hydrogen nuclear magnetic resonance spectroscopy both for the identification and quantitation of unknowns in wastewater.

Buttner et al.\textsuperscript{(131)} have developed an electrochemical sensor for in situ detection of TNT and other nitrated explosives. TNT, RDX, HMX, and other explosives are rapidly heated with a nichrome wire to 900 °C for a short period (~30 s). The explosive compounds

![Figure 15 Schematic of SCAPS.\textsuperscript{(39)}](image-url)
pyrolyze, producing NO. The NO fragment is detected by amperometry. The NO concentration is correlated with explosives concentration. They installed this sensor in a SCAPS probe and demonstrated its capabilities for field measurements.

Charles et al.\(^{132}\) have reported their progress on development of a continuous flow, fluorescence-based immunosensor for detection of explosives (TNT and RDX). Antibodies specific to the pollutant of interest are covalently immobilized in a micro column, which is then saturated with a fluorescent analog of the pollutant. When the pollutant of interest is injected into the micro column, it displays the fluorescent analog which is subsequently detected by an on-line fluorometer. LODs for TNT and RDX are 20 ppb. Their sensor was demonstrated on-site using samples collected at two military bases.

6 FUTURE DEVELOPMENT

Detection of explosives is mainly divided into three major areas, all of which have their own difficulties. The first is forensic investigation of crimes; the second is detection to prevent terrorist activity; and the third is detection to address environmental and/or public health concerns. Although several techniques have recently been evaluated for explosives detection as described in the previous sections, further work is still needed to improve them before they will be routinely used with confidence for nonforensic investigations.

With regard to forensic identification of explosive materials, several optical- and laser-based techniques (such as IR and Raman spectroscopy) are now sufficiently developed that they can be routinely used in the better equipped forensic laboratories for screening and/or confirmatory measurements. The main impediment for their further adoption is the need for automation of detection and analysis.

The present airport security check is performed by monitoring the shape and size of explosive packages inside suitcases or by using dogs to detect vapors emitted by explosive materials. These provide the initial information for human evaluation of the suspected bag or site. Based on the success with dogs, vapor-phase detection techniques should be improved to monitor on-line and in real time luggage and packages in airports and other security locations. As mentioned before, low vapor pressure and concealing explosive materials in packages reduces explosive vapors to very low concentrations for detection. The sensitivity of vapor detection needs to be further improved. This can be achieved by developing new technologies or improving current ones. Further work is also needed on fast, near real-time pre-concentration techniques that can improve detection sensitivity.

The selectivity of the explosives detection techniques needs further attention. A few techniques being evaluated (such as PF/LIF, PF/PI, REMPI, and IMS) are based on the detection of fragmentation products. Most of the fragmentation detection techniques lack selectivity. A farmer or gardener who works with fertilizer might provide nitro compound vapors, giving a false alarm when traveling though a security area. Additional work is needed to characterize the fragmentation processes from different explosives and other nitro compounds. Detection techniques can be improved by monitoring more than one fragment species and correlating the fragments with specific explosive materials. Thus work is also needed to enhance data acquisition and analysis in order to provide information in near real time by correlating the fragment concentrations. This will help in increasing traffic flow at airports and other security places. Improved detection will provide rapid information about the presence of explosive materials so that safety measures can be taken in time to avoid accidents or terrorist activities.

The third major area of explosives detection is environmental monitoring in the condensed phase. Measuring explosives in soil and groundwater has to be accomplished in the presence of major interferences, because soil is a very complicated medium in which the matrix can vary rapidly and unexpectedly from place to place at monitoring sites. Most of the evaluated explosives detection techniques recently developed for screening suspected sites have major problems with selectivity – while they indicate the presence of a nitro compound (and its concentration), they are usually not specific as to which nitro compound is present. Techniques for monitoring explosive vapors from condensed-phase samples can have even further complications due to interferences from more volatile compounds. The area of vapor detection needs further attention. Further work is needed towards the development of biochemical and laser-based techniques for explosives detection. Both sensitivity and selectivity of the techniques need further studies. Tagging of explosives with higher vapor pressure additives will help with the detection of new explosive packages.\(^{133}\)

Automation of detection and analysis is essential for developing the instruments described here into systems that can be routinely used in practical situations. Extensive efforts are currently under way to combine signal recognition through the use of neural network techniques with instruments capable of continuous monitoring.

Laser mass spectrometry (laser-MS) in molecular trace analysis involves two analytical tools: Ultraviolet (UV)-spectroscopy in the gas phase and time-of-flight mass selection. Both tools are combined by resonance-enhanced multiphoton ionization (REMPI). This type of mass spectrometry is therefore called resonant laser-MS in the following text. The special features of resonant laser-MS are high selectivity, rapidity, multicomponent capacity, and adaptability for application to many different problems. Beneath the fundamental principle of this analytical technique (i.e. REMPI and time-of-flight mass selection) several options are described in this article, such as medium or high resolution of mass selection and UV-spectroscopy. These options allow more or less sophisticated instrumentation and optimized adaptation to specific analytical problems. The reader will be introduced to the principles of resonant laser-MS and then to its history and the state-of-the-art of its application. This organization should help the reader to recognize the importance of the early experiments and of modern tendencies for application of laser-MS in trace analysis. The large experimental and instrumental variety and the tables of numerous researchers and applications presented in section 3 may demonstrate the flexibility and growing acceptance of resonant laser-MS. The examples presented, which illustrate the usefulness of resonant laser-MS in practice, include on-line trace analysis of emissions from combustion processes, e.g. from combustion engines or municipal incinerators. The article ends with a discussion of possible calibration processes, detection limits, and a summary of specific features.

1 INTRODUCTION

The combination of lasers and mass spectrometry has been widely accepted in research as well as in industrial laboratories in the form of matrix-assisted laser desorption/ionization (MALDI) for the detection of large biological molecules\(^{(1,2)}\) and also of laser ablation for elemental analysis of surfaces.\(^{(3,4)}\) However, for
the application of laser-MS in trace analysis (particularly in molecular trace analysis, which is the main subject of this article) only insufficient selectivity can be achieved by mass spectrometric means alone, and an additional species-selective discrimination is necessary. For this reason, in conventional mass spectrometry, the highly sophisticated technique of coupled gas chromatography/mass spectrometry (GC/MS) has been developed. This is a two-dimensional spectrometric method applying the selection parameters retention time and mass. Its twofold selectivity has permitted the sensitivity of conventional ultratrace analysis of complex mixtures to be extended to extremely low detection limits. Extensive, time-consuming and laboratory-bound procedures for sample preparation have to be accepted, though. New methods of trace analysis, which may not be capable of reaching these low detection limits, but exhibit short detection times and possibly significant levels of mobility, are thus needed. In particular, trace analysis, which is planned for incorporation into industrial processes for the purpose of feedback control, or which is needed for the analysis of strongly fluctuating emissions of gases, or which should permit the attainment of fast results in the case of chemical accidents, ought to be able to be performed on a timescale of minutes or even seconds. However, even a performance speed in the region of 1 h would represent progress in many cases. Laser-MS using pulsed lasers and time-of-flight mass analyzers (one mass spectrum for every laser pulse) fulfills the requirement of rapidity exceptionally well. With regard to the requirement of two-dimensional selectivity, a new option is possible in laser-MS, which is not available in conventional mass spectrometry.

This option is resonant laser-MS, which combines the two analytical tools, UV spectroscopy (in the gas phase) and mass spectrometry (time-of-flight). The combining element is REMPI. Several modes of laser-MS are possible in trace analysis, e.g. involving high or reduced resolution of UV spectroscopy and mass selection. In the case of actual industrial tasks of chemical analysis (e.g. arising in test facilities of the automobile industry or in municipal incinerators) we found that in addition

**Figure 1** The first mass spectrum (a) and UV spectrum (b) of a polyatomic molecule (benzene) measured using a resonant laser-MS apparatus employing laser light with tunable wavelength. (a) Mass spectra of benzene in its natural isotopic mixture taken at two excitation energies. In the right mass spectrum the abundant mass 78 is suppressed, thus relatively enhancing the \( ^{13}\text{C}^{12}\text{C}_6\text{H}_6 \) isotopomer. (b) Mass-selective UV spectra taken at the two masses 78 and 79 for abundant and \( ^{13}\text{C} \)-substituted benzene. The lower spectrum demonstrates that even in a mixture of components pure UV spectra can be measured for one selected trace component. It should be noted that these experiments were performed at a very early stage in the development of laser technology and of the adaptation of laser ionization in mass analyzers.
to high-resolution laser-MS the version with reduced UV
and mass resolution is of particular practical use. Most of
the applications presented in section 4 have been achieved
using this option. The high-resolution version of laser-MS
is necessary for specific problems, such as discriminating
between structural isomers (e.g. traces of chlorinated
aromatics within highly complex gas mixtures) or even
isobaric isotopomers.

To illustrate the two-dimensional selectivity of laser-
MS, an early mass-selected resonance ionization spectrum
is presented in Figure 1 together with a REMPI mass
spectrum.\(^5,6\) Both of these, the mass-selected laser spec-
trum and the spectroscopically enhanced mass spectrum,
may be considered as being complementary, with either
the mass or the laser wavelength fixed, and the other
parameter being freely variable. The resonance ioniza-
tion spectra in Figure 1(b) were recorded mass selectively
(at 78 and 79 u), and show the \(S_1(v_S)=S_0(0)\) transition
of the abundant \(^{12}\text{C}_6\text{H}_6\) and the rare \(^{13}\text{C}^{12}\text{C}_5\text{H}_6\) natural iso-
 topsomer. They reveal an isotopic shift of \(\Delta \nu = 4 \pm 2 \text{ cm}^{-1}\)
for the \(v_S\) vibronic band. This shift is sufficiently large to
selectively excite these two isotopomers. In Figure 1(a),
two UV resonance-selected mass spectra are shown which
were produced by REMPI at 38 620.5 and 38 622.4 cm\(^{-1}\).
The latter represents the band maximum position of the
79 u selective laser spectrum and clearly demonstrates a
significant relative enhancement of the heavier mass in
the mass spectrum.

Furthermore, the mass peaks in Figure 1(a) exhibit a
wing to smaller masses, producing a considerable broad-
ening of the peak and a reduction in mass resolution.
This is not due to an intrinsically small resolution in the
quadrupole mass analyzer used for this experiment, but
rather to metastable decay induced by photon absorption
during laser ionization. This effect, which was observed
very early without its origin being recognized, shines light
on a different feature of resonance-enhanced ionization,
and concerns fragmentation and metastable decay. A
renaissance in ion kinetic decay studies and the develop-
ment of new methods and new applications have been
initiated by this feature. The possibility of producing
both surprisingly soft and exceptionally hard ionization
was recognized already in the earliest stages of develop-
ment of resonance ionization and mass selection. Its high
sensitivity (e.g. one atom detection) and high selectivity
(isomer-selective ionization) represent further remark-
able characteristics. In the meantime, the importance of
mass-selective laser spectroscopy and optically selected
mass spectrometry for trace analysis has been recognized.

The method of resonant laser-MS has been so suc-
cessfully introduced into research laboratories that an
extensive body of survey literature already exists, e.g.
an introduction to lasers in chemical analysis and
mass spectrometry.\(^7\) a perspective of molecular
spectroscopy by resonance ionization and characterization
of molecules with regard to their behavior during this
ionization method.\(^14\)–\(^24\) resonant laser-MS,\(^12\)–\(^20\) and
resonance ionization mass spectrometry of atoms.\(^31\)–\(^33\)

The objective of this article is to provide an intro-
duction to the principles and possibilities of resonant
laser-MS, applied in molecular trace analysis. Therefore,
in section 2, the scientific and technical features of the
method are introduced. In section 3, the initial stages
of resonant laser-MS and its modern developments are
presented. The large range of subjects, accessible molec-
ular species, and research groups demonstrate the wide
distribution and acceptance of this method. In section 4,
examples from our own work have been selected to illus-
strate the versatility of laser-MS. Of course, these examples
do not cover all the possibilities and facets of resonant
laser-MS in trace analysis exploited and developed by the
many research active groups in this field. They rather are
intended to provide a first insight rather than an overall
review, the latter being disproportionate in terms of an
introduction to the method. Finally, in section 5, calibra-
tion methods, detection limits, and special features of
applied resonant laser-MS are discussed.

2 RESONANT LASER MASS
SPECTROMETRY: SCIENTIFIC
AND TECHNICAL PRINCIPLE

2.1 Resonance-enhanced Multiphoton Ionization

The combining of laser spectroscopy with mass spec-
trometry to provide a real two-dimensional analytical
tool is made possible by REMPI. On the one hand,
this laser-induced process is used to produce the ions
which are needed for mass spectrometry; on the other
hand, resonant intermediate states, which enhance this
ionization process, intrinsically involve molecular UV
spectroscopy. The principle behind REMPI is presented
in Figure 2: a UV photon is absorbed exciting a higher
energy level of the neutral molecule. A second pho-
ton is absorbed, which reaches above the molecular
ionization threshold. This \((1 + 1)\) ionization represents
the most effective multiphoton-ionization (MPI) pro-
cess. However, this process is not generally applicable,
e.g. it cannot be used for some small molecules or
alkanes. This is due to unfavorable energies of the
accessible intermediate states and of the ionization
threshold. In this case, MPI processes of a higher order
have to be used, such as \((2 + 1)\) multiphoton absorp-
tion (see Figure 2a). All these processes involve the
molecular spectroscopy of neutral intermediate states
(see Figure 2b). Each molecule has its own character-
istic UV absorption spectrum. Using an appropriate

laser wavelength, selective absorption and (by resonant MPI) selective ionization of a particular molecule can be achieved (Figure 2c). Thus, trace species can be analyzed selectively by REMPI within a gas mixture consisting of many other components in considerably larger concentrations.

In contrast to atoms, with their low number of energy states and narrow absorption bands, the density of states in molecules is considerably larger. This often results in heavily congested spectra, with regions of broad, unstructured absorption bands, particularly at higher temperatures (e.g. 500 K). As a result, selectivity is reduced. The advantage of this in itself unfavorable factor is that it enables synchronous analysis of several preselected trace components, due to an accidental overlapping of the molecular absorption bands. The molecular absorption cross-sections are smaller than typical atomic ones, to a level of several orders of magnitude, but nevertheless sufficient to provide high sensitivity. Typical ionization yields [ratio of the number of ionized molecules to the total number of molecules within the laser focus\(^{(36)}\)] are \(10^{-2}\) for \((1 + 1)\) MPI and \(10^{-5}\) for \((2 + 1)\) MPI. These can be enhanced by increasing laser intensities. However, at higher laser intensities, which may be necessary for higher-order MPI processes, multiphoton-induced fragmentation takes place\(^{(35,36)}\) in addition to ionization, reducing selectivity considerably. Therefore, laser wavelength and intensity have to be chosen carefully, in order to prevent fragments from other molecules from overlapping with the molecules of interest, within a mass spectrum. Other unfavorable effects, which may reduce ionization efficiency significantly, are...
fast relaxation processes affecting the resonant intermediate electronic state or unfavorable Franck–Condon factors of the first or second absorption step. In the case of these occurring, alternative intermediate states or MPI schemes have to be chosen, or techniques such as species-specific fragment ion detection (57) pre-selection by fast gas chromatography (GC) and, in particular, application of femtosecond lasers (22) have to be involved.

2.2 Time-of-flight Mass Spectrometry

For REMPI of molecules, mostly pulsed lasers are used. This permits ion production within a short time and in small volumes, these being ideal preconditions for time-of-flight mass spectrometry (TOFMS). In pulsed laser ion sources, the ions are usually produced in a static electric field. These are accelerated at the moment of ionization, and reach a field-free drift tube after some microseconds. As all ions are produced within the confines of a very small volume, and therefore at nearly the same electrical potential, they have very similar kinetic energies in the field-free drift region. As a result, the velocities, and therefore the flight times of the ions, are proportional to the square root of the mass. Finally, the ion current measured as a function of time supplies mass information about the ionized species. A schematic view of a time-of-flight (reflection) mass analyzer is shown in Figure 3. Several factors, such as a finite volume of the laser focus, initial velocities of the neutral molecules and space charge effects, result in a wider distribution of kinetic energy and therefore in an increased distribution of flight times. This reduces the mass resolution, and is a well-known problem in linear time-of-flight mass spectrometers (26,38).

The so-called reflectron time-of-flight mass analyzer (26,39) compensates for most of these factors by reflection of the ions within a special reflecting field. The principles of its operation are as follows. The originally diverging ion clouds are compressed at the space focus of the pulsed ion source. The ion reflector projects this space focus onto the surface of the ion detector. This results in short ion pulses at long ion flight times, thus providing high mass resolution. This principle is indicated in Figure 3 by the different widths of the ion clouds in front of, inside, and behind the ion reflector. An optimal mass resolution as high as \( R(50\%) = 20\,000 \) (26,40,41) has been achieved in this way. The routine mass resolution of reflectrons lies in the range \( R(50\%) = 3000–5000 \). A very good mass resolution helps to achieve not only efficient mass selection, but also a good signal-to-noise ratio: the ions investigated appear within a very narrow time window (e.g. 10–20 ns) while background signals are randomly distributed.

Figure 3 Schematic diagram of the laser mass spectrometer consisting of the neutral source (gas inlet), the ion source (ion optics, position of laser ionization), time-of-flight regions for mass separation, the ion reflector for compensation of time-of-flight distribution (high mass resolution), and the ion detector. For two-color ionization a second laser wavelength is needed which can generally be provided by the pump laser of the tunable laser source for resonant excitation of the molecular intermediate states (first laser wavelength fully tunable, second laser wavelength harmonics of neodymium–yttrium-aluminum garnet (Nd : YAG) laser: 355, 266 or 213 nm).
distributed over a large time region (e.g. 100 ms). As indicated in Figure 3, there is also a special location within the field-free drift region, the so-called space focus. This is a typical feature of pulsed ion sources and represents a point of maximum ion pulse compression, and therefore also of optimized mass resolution. By secondary excitation, with laser-induced fragmentation, a type of tandem mass spectrometry is achieved without any major change necessary in the reflectron time-of-flight spectrometer itself.

Further to high sensitivity and good mass resolution, speed is another specific beneficial feature of reflectron time-of-flight mass spectrometers. Each ionizing laser pulse produces a complete mass spectrum. In principle, the repetition rate is limited by the overlap of two consecutive mass spectra. A repetition rate of 10 kHz could be achieved, limited by the typical flight times of the slowest ions of some 100 µs. Until now, suitable lasers with such a high repetition rate have not been available; besides this, the temporal behavior of typical gas inlet systems does not allow such a high time resolution. We have achieved a repetition rate of 100 Hz with available pulsed lasers and mass spectrometers fitted with a special gas inlet system. An additional advantage of time-of-flight mass analyzers is their simple and sturdy construction.

2.3 The Combining of Resonant Laser Ionization and Reflectron

The combination of these two methods results in a two-dimensional analysis technique applying the parameters of laser wavelength and mass. The choice of the suitable wavelength allows species-selective ionization, and enhances the discrimination of chemical compounds which cannot be separated by means of their mass alone. An illustrative example of this is the carbon monoxide (CO) in the exhaust emissions of motor cars. CO has the same nominal mass as nitrogen but is much less abundant there. Whereas CO is easily ionized at 230 nm, N₂ does not show any noticeable degree of ionization efficiency at all at this wavelength. Some further typical exhaust components with identical nominal masses are, for example, formaldehyde, ethane, and nitrogen monoxide with a mass of 30; acetaldehyde, carbon dioxide, and dinitrogen oxide with a mass of 44; propionaldehyde and acetone with a mass of 58; polycyclic and substituted aromatics with all their isomers and fragments, e.g. the harmless perylene and the carcinogenic benzo[a]pyrene, both with a mass of 252.

Without selective ionization, these components can only be separated by means of extremely high mass resolution, which brings with it the disadvantages of reduced sensitivity and speed, and increased costs.

An example of a scenario for the combination of resonant ionization and laser-MS for trace analysis is the following case of motor exhaust gas monitoring. Typical points for the collection of gas samples are behind the valve (single-cylinder emission), and in front of and behind the catalytic converter. The exhaust gas, with its rapidly fluctuating concentrations of trace compounds, is guided into the mass spectrometer by means of a 6 mm tube of about 500 cm in length, and introduced into the ion source by a pulsed valve, forming supersonic molecular beams, or by a thin metal needle emitting effusive beams. Thus, parts of the sampled gas are channeled to the spot in the ion source, where the ionizing laser is focused. This laser is fired releasing pulses of typically 10 ns in pulse length. The laser pulse defines flight time $t = 0$, the time at which the ions start to be accelerated. They reach the ion detector after a flight time which is determined by their mass. When the slowest ion has arrived, a new gas pulse can enter the ion source and be ionized by the next laser pulse. By synchronizing the motor ignition cycle with the ionizing laser pulse, and delaying the laser pulse in relation to the motor cycle in steps (e.g. of a few milliseconds or less), even the temporal profile of concentrations in the original exhaust gas can be analyzed species selectively with a sub-millisecond time resolution, provided the conditions within the motor remain stable during this sampling process.

2.4 High-resolution Laser Ultraviolet Spectroscopy

UV spectroscopy in chemical analysis is mostly applied to compounds in solutions and therefore exhibits only minor species-selective information in comparison with methods such as infrared (IR) spectroscopy. For larger molecules [e.g. polycyclic aromatic hydrocarbons (PAHs)], even UV spectroscopy in the gas phase often does not supply good molecular fingerprints. This is due to low-frequency vibrations and rotational motion which are present in a highly excited state at room temperature. A typical example of this is the internal rotation of the two phenyl rings of biphenyl around their connecting single bond. Thus, the gas-phase UV spectrum of biphenyl is at room temperature totally congested and does not show any clear structure. These broadening effects impede the achievement of optimum spectral resolving power, and therefore of the selectivity which would be possible by means of UV spectroscopy (and consequently also REMPI).

Modern laser UV spectroscopy, however, often provides a well separated fine structure which is comparable to or has even better resolution than in IR spectroscopy. This is achieved by cooling the molecules in an isenthalpic gas expansion produced by an external pressure of several bar which expands into a vacuum through a narrow hole (e.g. width 0.2 mm, length 1 mm); in this way a so-called
supersonic beam is formed. During the expansion process, low-frequency vibrational and rotational motions freeze out (rotational quasi-temperatures below 10 K are achievable) without condensation of the gas molecules occurring. This reduces the number of possible vibronic transitions, and therefore also the number of lines in the UV spectrum, considerably. In addition, these lines exhibit a significant narrowing of their line width, due to the rotational cooling. The effect of cooling in a supersonic molecular beam is illustrated in Figure 4, which shows the vibrationless electronic origin of the $S_1-S_0$ transition of one of the three different monochloro anthracene isomers. These spectra were measured using resonance ionization spectroscopy in an effusive beam at room temperature (Figure 4, top trace) and in a supersonic beam (Figure 4, bottom trace). The significant narrowing of the vibronic band is obvious. This is due to the lower level of rotational excitation in the $S_0$ ground state, and therefore to the occurrence of fewer transitions contributing to the rotational envelope of this band.

To generate such a supersonic molecular beam one uses mostly Ar or He as the carrier gas, with the molecule of interest seeded into this. To avoid putting the vacuum system under a too heavy load, instead of a continuous gas inlet, pulsed expansion is used, delivering gas pulses of typically 0.2 ms duration at a rate of repetition of 20–50 Hz (compatible with typical pulsed laser repetition rates). Even molecules with low vapor pressure can be investigated, by means of high-temperature valves, which, nevertheless, allow sufficient cooling of internal molecular degrees of freedom.

Figure 4  Illustration of the effects of supersonic beam cooling on the structure of molecular spectra (here 2-chloroanthracene). Top trace, effusive beam at room temperature; bottom trace, supersonic beam at less than 20 K rotational quasi-temperature.

Figure 5 (a) Supersonic beam UV absorption spectra for three isomers of dichlorobiphenyl. Isomer-selective laser excitation is possible for instance at the marked wavelengths $\lambda_1$, $\lambda_2$, and $\lambda_3$. These spectra were taken by resonance ionization spectroscopy [see Figure 2b] using two-color excitation; this is possible with one single laser system (dye laser pumped by an Nd/YAG laser): the first, tunable wavelength is achieved using the dye laser, while the second fixed wavelength can be obtained from the pumping Nd/YAG laser. This allows for higher ionization efficiency and the achieving of low-lying, but sharp and therefore highly selective intermediate states in the resonant ionization process. (b) Schematic diagram of the supersonic beam arrangement with pulsed valve, skimmer and pressure regimes.

Today, supersonic beam spectroscopy represents a highly effective technique and has been successfully introduced in laboratories for molecular physics. Its virtues for analytical applications were recognized at an early stage. Very well structured and simplified molecular spectra now even allow isomer selection, e.g. of large aromatic molecules. As an example, Figure 5 shows the laser ionization spectra (comparable to UV absorption spectra) of three dichlorobiphenyl isomers. The spectra are
well structured, making it possible to find excitation wave-
lengths (e.g. $\lambda_1$, $\lambda_2$, and $\lambda_3$) at which every single isomer
can be excited and ionized selectively. Isomer selectivity
has been achieved for many different PAHs (e.g. pery-
lene and benzo[\(a\)]pyrene) and for chlorinated aromatics.
Depending on the special analytical problem involved,
one may choose high-resolution REMPI with supersonic
beams or medium-resolution REMPI with effusive mole-
cular beams. The latter is sufficient if polycyclic and
substituted aromatics are to be monitored as a class
of chemical compounds contained within a complex
mixture of pollutants (e.g. in emissions from industrial
combustion processes) but without isomer selectivity.
Medium-resolution REMPI is also sufficient for trace
analysis of emissions from combustion engines.

2.5 Gas Inlet System

Suitable sampling is crucial for reliable trace analysis.
Since mass spectrometry is primarily a gas analytical tool,
it is well suited for trace analysis of gaseous emissions. One
major problem arises from the large pressure differences
between atmospheric pressure samples and the vacuum
system ($<10^{-3}$ bar). Special means of pressure reduction
are required, although at the point of ionization (defined
by the laser beam) the gas density should be as high as
possible. The only way to fulfill these conditions is to
use molecular beams which can be produced in different
ways. Examples of these arrangements are described in
the following. Effusive continuous molecular beams
can be formed using a thin metallic needle (e.g. 3 cm
long, 0.5 mm inner diameter). This needle reaches into
the ion source; its end is positioned near the axis of the
electrode arrangement making laser ionization possible
about 1 mm below the end of the tubing (minimum spatial
broadening of the molecular beam) and, simultaneously,
on the electrode axis (optimum ion trajectory) (see
Figure 6a).

However, thin needles do not reduce the total gas flow
sufficiently if a gas pressure of 1 bar or more is applied on
the high-pressure side. Therefore, these have to be opened
periodically for short intervals or the use of an additional
pressure reduction system is necessary. In Figure 6(a),
diagrams of both versions are shown with a U-shaped
by-pass for the sample gas. In Figure 6(b), a supersonic
beam gas inlet is presented; a small nozzle (0.2-mm inner
diameter, 1-mm length) is periodically opened for very
short times ($<200$ $\mu$s). On the high-pressure side several
bar may be applied. The large pressure drop to the vacuum
side of the nozzle enables the formation of a supersonic
beam. The special features of this gas inlet have been
described in section 2.4. Additional pressure reduction,
which is mostly necessary due to the large gas load of
supersonic beams, is achieved by using a skimmer and
a separate vacuum chamber. Unfortunately, this results
in a large distance between beam nozzle and point of
ionization, and therefore a reduced concentration at the
laser focus. An improvement of this situation can be
achieved using an in-line arrangement of the molecular
beam as shown in Figure 6(c).

In Figure 6(d), a further important version of the set-up
is presented, the combination of a supersonic molecular
beam with laser desorption of neutral molecules. The
latter can be selectively ionized by means of laser light
and mass-selectively detected. Many applications are
possible or have been put into use already, such as the
study of biomolecules, analysis of solids and surfaces,
testing of semiconductor surfaces for organic pollutants,
or analysis of soil samples for dangerous polycyclic or
substituted aromatics (see section 3). In addition, the
combination of a supersonic beam valve with a GC
capillary has been realized as shown in Figure 6(e). A
special construction for this coupling is necessary to avoid
first the reduction of GC resolution due to gas diffusion
in slits and dead volumes or due to reduced gas flow, and
second the inefficient cooling of the supersonic beam due
to unfavorable pressure conditions.

Of course, it is of fundamental importance to use heated
gas inlet systems for larger molecules, e.g. chlorinated or
polycyclic aromatics. This can be achieved in resonant
laser-MS with commercial heated transfer lines, heating
within the vacuum system, optimum heat conductance to
the very end of the gas beam-emitting device (needle or
valve), and avoidance of any kind of cold spots (e.g. at
the transit of gas lines through vacuum flanges).

3 HISTORICAL RETROSPECTIVE AND
MODERN DEVELOPMENTS WITH
RELEVANCE TO TRACE ANALYSIS

Already in the first 4–5 years since its introduction, most
features of resonant laser-MS of molecules have been
defined and studied and the foundations for most of
the later steps of its development have already been
laid at this early stage. By presenting these features,
developments, and current topics of interest relating
to trace analysis in three tables, together with the
research groups involved, with particular work cited in
the bibliography, and a summarizing discussion, we hope
to provide an informative survey without overwhelming
the reader with too many details. In this respect we would
like to apologize for the fact that not all groups working
in the field of resonant laser-MS with relevance to trace
analysis could be mentioned in this survey.

Successful laser-induced (although not resonance-
enhanced) ionization of molecules in the gas phase
Figure 6 Different gas inlet systems for the supply of neutral sample molecules in the isolated gas phase, necessary for resonant laser ionization and time-of-flight mass analysis.
followed by mass selection was reported on as early as 1970 (Table 1). Resonant laser ionization was applied to molecules 5 years later. The method was introduced as a new means for UV and visible molecular spectroscopy rather than mass spectrometry. Even its combination with mass selection was originally rather a further step towards a new form of molecular spectroscopy. In this context, it is interesting to observe that another new technique, namely the cooling of molecular rotational and vibrational internal motions in a supersonic gas beam, revolutionized molecular spectroscopy. It did not take long for resonant laser ionization and supersonic molecular beams to be combined, thus starting a fruitful period of molecular spectroscopy on larger molecules.

While the first application of laser ionization [both resonant(48–52) and non-resonant(45,46)] was on small, mostly two-atom molecules, first mass-selective laser ionization experiments on polyatomic molecules were reported in 1977 and 1978. The first polyatomics were benzaldehyde, benzophenone, and nitrotoluene, which were still ionized using a fixed-frequency laser, and benzene, for the ionization of which the wavelength of a dye laser was tuned to its $S_1(V_0)\rightarrow S_0$ transition. These experiments were followed by many publications on all kinds of molecules, their mass-selected laser spectroscopy or spectroscopically selected mass spectra. Already in the early years of REMPI (1982–85) several groups therefore tried to characterize molecules according to their behavior under resonant laser ionization conditions.

Two outstanding features of resonant laser ionization – very soft ionization and variability from metastable decay to extreme fragmentation – were already detected in the first experiments. Therefore, several research groups went on to investigate the mechanisms of fragment ion formation during resonant laser ionization.

Different methods have been used to this purpose, such as secondary fragment ion excitation using a time-delayed second laser (representing the first steps towards tandem laser-MS), a new kind of photoelectron spectroscopy revealing fast intramolecular processes in the neutral intermediate state, and picosecond laser excitation. In fact, in addition to molecular spectroscopy, the new tool of resonant laser ionization has been applied mainly to the study of internal molecular dynamic processes.

The combination of resonant laser-MS with other techniques proved to be an important factor in its development since the very beginning. In this respect, some early experiments are listed in Table 2. The combination with supersonic molecular beams has already been mentioned above; its special features and benefits are presented in section 2.4. In addition to providing the possibility of performing isomer- and even isotopomer-selective molecular ionization, it was also able to deliver important spectroscopic information (a prerequisite for highly selective resonant laser ionization) about larger molecules. Another intriguing early combination was that with GC. On the one hand, this allows the GC of very complex gas mixtures without the need for laborious chemical separation of interfering species in advance (due to the high level of selective detection achieved by resonant laser-MS). On the other hand, this combination permits to quantify or calibrate resonant laser mass spectra, or to test its sensitivity.

In Table 2, some citations are given under the heading Resonance ionization of molecules and trace analysis. Again, very early, the advantages and new possibilities of resonant laser ionization for ultratrace analysis were recognized and detection limits for aniline, and NO were reported between 1979 and 1981. Another important technique performed in combination with resonant laser-MS is reflectron TOFMS (see also sections 2.2 and 2.3). In addition to high mass resolution, new means of performing tandem mass spectrometry and of studying and putting into practical application of metastable decay of molecular ions were provided by this combination. Since resonant laser ionization also permits the enhancement of metastable decay (as mentioned above; see also Figure 1), the connection of both methods proved to be very promising.

A third combined technique is neutral laser desorption in a resonant laser mass spectrometer. Its different facets such as picosecond laser desorption, supersonic

Beam cooling of desorbed neutral molecules\(^{83-86}\) and application to large biomolecules\(^{82,86-88}\) were exploited at an early stage. By contrast with the other laser-MS method for solids, MALDI (see Introduction), resonant laser-MS of laser-desorbed neutrals is more suitable for trace analysis of complex mixtures of solid samples. This is due to its two-dimensional selectivity. It is not unexpected that laser desorption resonant laser ionization mass spectrometry has developed into an important field of research within its own right, with many highly interesting applications.

Another early combination,\(^{89-91}\) namely that of picosecond lasers and resonant laser ionization, should also be mentioned. This has been applied to study fast intramolecular processes in the neutral intermediate states. These processes may reduce ionization efficiency.

</table>
Their study, and means of surpassing these effects, are also of importance for laser-MS in trace analysis. Recently, very short high-intensity laser pulses (femtosecond lasers) have been used for this purpose, thus closing the cycle which began with the early short pulse experiments.\(^{89-91}\)

Whereas Tables 1 and 2 summarize experiments and developments of the beginning of resonant laser-MS, Table 3 presents recent and future tendencies in the development of resonant laser-MS which have a significant relevance to trace analysis. Numerous research groups (see Table 3) are using the technique in all kinds of trace analysis applications.

Supersonic beams play an increasingly important role in achieving highly selective trace analysis. This is true for pure spectroscopy and also for its combination with resonance MPI. Not a scientific technical step of development, but rather a very concrete field of application, is the analysis of combustion processes. In the process of combustion, hundreds of different components in the gas phase are produced, in significantly varying concentrations. Highly selective, sensitive, on-line detection methods are necessary to monitor these emissions. Resonant laser-MS fulfills these conditions, and has been applied to study flames, rough and flue gas in waste incineration plants, and exhaust emissions from motor cars.

Since femtosecond lasers have become commercially available, their use in resonant laser-MS has increased considerably. The hope is to achieve high ionization efficiencies also for problematic molecules such as nitroaromatics and metallo-organic compounds. Fast internal molecular processes mostly represent the reason for the problematic nature of these molecules. Another means of overcoming these problems involved single-step photoionization by laser-induced vacuum UV light, putting up with reduced or even lost selectivity. A comparison of vacuum UV and femtosecond laser ionization, which likewise does not allow very high selectivity either, has been published.\(^{131}\)

A third way to overcome these problems is to introduce a further parameter of selectivity, such as the retention time of a GC capillary, and detect fragment ions if dissociation processes in the neutral molecules are involved in the ionization process. Thus, for instance, nitroaromatics can be separated by the GC capillary while selective NO monitoring by resonant laser-MS may discriminate between all other trace compounds in the untreated sample. However, GC resonant laser-MS is of considerable interest as a method of extreme selectivity, as well as an extension of GC itself.

Another combination technique which represents a subject of increasing popularity within the community of laser-MS researchers and users is laser desorption resonant laser-MS. Although this has not achieved the same level of importance as MALDI (no separate ionization step there), it is much more appropriate for trace analysis and has been applied to many interesting problems. Examples are the comparison of aerosol particles near busy roads and from industrial areas (with regard to their PAH content)\(^{152}\) and the detection of organic molecules in extraterrestrial (meteoric) particles.\(^{113,154}\) Different variations of this technique have been studied, such as combination with supersonic beams, desorption from frozen samples and the comparison of thermal and laser desorption.

Although this article is not directly concerned with atomic trace analysis, we want to mention at least a few important topics in this respect. (This is not representative for atom detection by resonant laser ionization.) Since atoms usually show much higher ionization efficiencies than molecules, single-atom detection was discussed, studied and acclaimed at a very early stage. Extremely sensitive and selectivity have been demonstrated for strontium and plutonium detection.\(^{168,169}\) Not extreme trace analysis, but rather elemental analysis of solids and surfaces, is the goal of combined laser ablation and resonant laser ionization.\(^{170,171}\)

### 4 APPLICATION TO TRACE ANALYSIS OF COMPLEX CHEMICAL MIXTURES

**4.1 Application to Trace Analysis of Exhaust Emissions from Motor Cars: Dynamic Processes Behind the Combustion Chamber and in the Catalytic Converter**

For all measurements presented in this section,\(^{118,172,173}\) a medium-resolution linear time-of-flight mass analyzer was used. The ionizing laser wavelength was either 363 nm (for simultaneous NO and acetaldehyde monitoring) or 266 nm at which most aromatics but not other hydrocarbons absorb. In Figure 7, fast on-line measurements of the concentrations of acetaldehyde and nitrogen monoxide in the exhaust gas under rapidly changing motor conditions (speed and load) are shown. The laser repetition rate was 50 Hz, giving a maximum time resolution of 20 ms. Whereas NO is a product of total combustion of hydrocarbons, acetaldehyde production is due to incomplete combustion and is formed from ethanol contributions (important for alternative fuels). We found that products of total and partial combustion usually show the same temporal behavior when speed and load are synchronously changed (corresponding to a car moving with traffic). However, under special conditions (in the case of Figure 7a rapid decrease of speed after exceeding 3000 min\(^{-1}\)) a strong emission peak of acetaldehyde is observed with a delay of 300 ms (this delay time was similar for different measurements on the same motor). Together with other observations, this indicates that the acetaldehyde peak in Figure 7 is not due to direct internal
The overall sum of emitted aromatics is considerable. A more or less constant ratio for the different compounds for all observed aromatics appear, which show a numerous short peaks of emission (of up to 300 ppm and the measurement made in front of the catalytic converter, has its origins in governmental regulations in the USA. In testing pollutant emissions from motorized vehicles and of well defined variations in velocity (see Figure 8c) for the FTP (federal test program) cycle. This is a program called if the speed has exceeded 3000 min valve. In fact, combustion is interrupted in the motor combustion, but rather to chemical reactions at very hot surfaces of the exhaust pipe directly after the emission valve. In fact, combustion is interrupted in the motor type investigated if the speed has exceeded 3000 min\(^{-1}\) and then suddenly decreased below this value. This is a means of regulation initiated by the motor electronics for gasoline-saving reasons.

In Figure 8, two measurements of aromatic compounds are shown, one taken in front of (Figure 8a) and one behind (Figure 8b) the catalytic converter of a motor car, at an industrial test facility. In particular, the concentrations of benzene, toluene, xylene, trimethylbenzene, and naphthalene were observed synchronously during a so-called FTP (federal test program) cycle. This is a program of well defined variations in velocity (see Figure 8c) for testing pollutant emissions from motorized vehicles and has its origins in governmental regulations in the USA. In the measurement made in front of the catalytic converter, numerous short peaks of emission (of up to 300 ppm and more) for all observed aromatics appear, which show a more or less constant ratio for the different compounds.

The contribution of these short emission peaks to the overall sum of emitted aromatics is considerable. A reduction of this “dynamic” part of the emission should reduce the concentrations of aromatics produced in the automobile exhaust significantly, at least in the case of city traffic. From other highly time-resolved measurements, we deduce that the origin of these peaks is to be found in motor-controlling effects. For instance, strong fluctuating pollutant concentrations have been observed when the oxygen content in the fuel mixture of regulated motors is subject to rapid changes.

The measurements behind the catalytic converter reveal a significant reduction in pollutant concentrations as expected. The emitted concentrations lie far below 10 ppm after a warming-up time of the converter of 200 s. It is interesting to note that in the first 10 s near-zero emissions are observed even in the cold converter, while the measurements in front of the catalytic converter (Figure 8a) show exceptionally high emissions during the first few seconds (corresponding to the starting phase of the engine). This effect may be explained by adsorption of the aromatics on the cold catalytic surfaces. After some delay, these surfaces are warm enough for the adsorbed aromatics to evaporate (see the emission peak after a delay time of >10 s in Figure 8b). The molecule-dependent delay times (the larger the molecule the larger the delay) observed in spectra with better time resolution support this explanation. Far more astonishing, however, is the appearance of emission peaks of benzene even for a hot catalytic converter, i.e. after 700 and 1200 s. In the latter case, the concentration even reaches a value of more than 100 ppm. In laboratory experiments, we found that under special conditions (i.e. high hydrogen or water, low oxygen concentrations) dealkylation takes place along with efficient production of benzene from alkylbenzenes. Even the formation of naphthalene has been observed. The assumption that these processes are the reason for the high benzene peaks is supported by the absence of corresponding significant peaks for the alkylated benzenes in Figure 8(b).

These few examples demonstrate that analytical techniques with high time resolution in the 10 ms range are necessary to detect and study fast dynamic effects in vehicle exhaust emissions and to improve the electronic control of motorized vehicles. Understanding the origins of pollutants both during and after combustion phases may help to reduce the pollutant concentrations in the exhaust; understanding the dynamic effects of electronic control may even help to reduce the total consumption of fuel. REMPI mass spectrometry is able to supply the necessary time resolution for such on-line studies and works for different trace compounds, e.g. aromatics, aldehydes, or typical catalytic converter products (e.g. HCS, CS\(_2\), OCS).
Figure 8  Concentration (ppm) of aromatics in the exhaust emission of a motor car (industrial test facility) measured (a) in front of and (b) behind the catalytic converter during a fixed-velocity program [FTP cycle (c)]. The rapid changes in motor operating conditions (speed, load, changing of gear) induce significant peaks of pollutant emission. Even within the catalytic converter, unfavorable chemical gas conditions may result in the formation and emission of peaks of aromatics (benzene, naphthalene) instead of preventing them.
4.2 Application to Trace Analysis of Exhaust Emissions from Motor Cars: Traces of Motor Oil in the Exhaust

In section 3, aromatic compounds originating in the fuel and appearing in the exhaust of combustion engines were investigated. However, motor oil too is a source of aromatic species in the exhaust, these being on average of larger molecular size. The first experiments to detect these motor oil-based emissions were performed on a hydrogen motor (a conventional combustion engine with minor changes to permit use of hydrogen as a fuel). All aromatics detected in the exhaust could therefore only be due to the motor oil. In Figure 9, two mass spectra are presented which were measured in the exhaust of a hydrogen motor, under two different sets of operating conditions. At the higher speed but lower load, the smaller masses up to 170 (mostly due to alkylated naphthalenes) are enhanced in contrast to the situation with lower speed but higher load. The overall concentration of all aromatics determined by conventional unselective methods was about 1 ppm. A sensitivity of less than 10 ppb for most of these aromatics can be deduced from this value along with the intensity distribution presented in Figure 9. Again, a small, medium-resolution linear time-of-flight spectrometer and a semiselective laser wavelength of 266 nm are sufficient for this analysis.

In Figure 10, the attempt to perform the same measurement on a combustion engine working with conventional gasoline as fuel is presented. From the bottom trace, one realizes that above a mass of 150 there is practically no signal, whereas between mass 90 and 130 exceptionally large peaks occur, which obviously saturate the ion detector, and represent unburned compounds from the fuel. By using a pulsed mass filter (pulsed deflection plates located after the ion source in the field-free drift region), this

![Figure 9](image9.png)

**Figure 9** Aromatic compounds in the exhaust emissions of a combustion engine (hydrogen motor) resulting mainly from emissions from the motor oil film coating the combustion chamber. The mass spectra were measured using two different sets of parameters (speed, load) revealing significant variations in the relative concentrations of masses between 120 and 170 and between 170 and 240.

![Figure 10](image10.png)

**Figure 10** Aromatic compounds in the exhaust of a combustion engine (conventional gasoline). Lower trace: unburned aromatic compounds from the fuel give rise to such high peaks that the ion detector saturates and higher masses disappear within the mass spectrum. Upper trace: by means of a pulsed mass gate, masses in the range from 60 to 130 are deflected, therefore do not reach the ion detector, and thus are eliminated from the mass spectrum; now, higher mass peaks appear. Good correlation with the peaks in Figure 9 and with experiments involving the introduction of tracer molecules into the motor oil, which are not present in the fuel, allow for an assignment of these higher mass peaks to emissions from the motor oil film coating the combustion chamber.
range of masses has been suppressed in the upper mass spectrum. Now, masses above 130 occur which correlate well with the mass peaks of Figure 9 and are classified as “motor-oil” peaks. This has been verified by measurements carried out under different motor conditions, by comparison with conventional methods under static motor conditions, and by the addition of tracer molecules to the motor oil which are not present in the fuel.

Besides information about the mechanism of oil consumption, these results can be used to determine the dynamic behavior of oil consumption, or to obtain quantitative values for it under many different static motor conditions, e.g. characterized by load and speed. Conventionally, oil consumption is measured by weighing, which is extremely time consuming and very expensive if performed for a number of pairs of parameters (i.e. load and speed). In Figure 11, a measurement of motor oil consumption is presented, which was performed by means of resonant laser-MS within the space of one day. Similar conventional measurements would take many weeks to be performed. The interpretation of Figure 11 is still in progress. Some effects such as oscillations for constant load but increasing speed indicate rotation and twisting of the piston rings which control the oil film on the inner wall of the combustion chamber. Other effects, e.g. the decrease in motor oil consumption at constant (high) speed and at high increasing load, indicate cracking of the oil compounds at high temperatures. It has been found (in measurements shown here) that under most motor conditions more than 90% of emitted oil compounds leave the combustion chamber unburned.

The examples given in this section illustrate that fast analytical methods represent a purposeful or even necessary approach not only from the point of view fast fluctuating concentrations but also from that of a large number of “data points”.

4.3 Application to Trace Analysis of Exhaust Emissions from Industrial Incinerators

Combustion processes causing air pollution are not present in combustion engines alone, they also occur on an industrial level, e.g. in the case of municipal incinerators. Gas cleaning after combustion is the most expensive element in such plants, and any degree of reduction

![Figure 11](image_url)  
**Figure 11** Measurement of the consumption of motor oil for the different pairs of parameters load (Nm) and speed (min⁻¹). Lines are shown for constant oil consumption (g h⁻¹). Notice the significant variations which occur at constant load or speed in certain parts of this figure; this allows conclusions to be drawn regarding the actual mechanical and chemical processes at work during and after combustion.
of these costs would be economically very productive. One way of achieving such economies is to monitor the combustion products and minimize pollutants produced (e.g. due to malfunction) by feedback control.

We performed measurements of the flue gas directly from the second combustion chamber of a pilot plant for waste incineration with 1 MW heating power.\textsuperscript{116,117} One goal of the pilot project was to optimize overall combustion by transition from a precombustion on the grate of the first combustion chamber to a gasification process. This step was to allow more complete combustion in the second chamber. Monitoring of the combustion products was to help one to perform this transition in an optimum way, to confirm the improved combustion conditions, and permit the carrying out of a control of the whole plant. The first such measurements are presented below. Figure 12, shows a mass spectrum taken at the second combustion chamber, with gas temperatures of 900 K. Details of the gas sampling can be found elsewhere.\textsuperscript{116,117} The combustion conditions were fairly unfavorable, giving rise to many different compounds in significant concentrations. In fact, this mass spectrum is a snapshot of trace concentrations which develop differently over time. For a more complete view of the situation one has to study concentration–time profiles.

Some such profiles are presented in Figure 13. They were obtained by centering time windows at the flight time of selected masses. In Figure 13, the masses 78 (benzene), 128 (naphthalene), 170 (alkylated naphthalenes), and 178 (phenanthrene) have been selected for presentation. These mass signals provide illustrative examples of how single species behave differently over time and under changing combustion conditions, e.g. the transition from combustion to gasification. This transition is indicated by three short, small concentration peaks of masses of 78 and 128 while the higher masses (170, 178) do not show corresponding fluctuations. In fact, phenanthrene even exhibits a significant but constant signal over the whole time, from the beginning of the measurement up to 500 s. At 500 s a malfunction in the post-combustion occurred, inducing a very strong increase in masses 78 and 128, strong oscillations in mass 170, and a remarkable decrease in phenanthrene production which lasted for more than 100 s. It took more than 300 s for the combustion to become stabilized again, this showing up as a decrease in masses 78 and 128 and a delayed decrease in mass 170. The behavior of mass 178 should be noted. At the supposed end of the malfunction near 800 s, the phenanthrene signal increased significantly and became the dominant signal in the mass spectrum (see Figure 12) for a further 800 s.

![Figure 12](image-url) On-line PAH-selective mass spectrum for the flue gas of a waste incinerator obtained using a resonant laser-MS instrument with a ionization wavelength of 248 nm (excimer laser). The sampling point was located directly at the postcombustion chamber, the gas temperature being 900 K. The recording time (and time resolution) was 0.5 s.
LASER MASS SPECTROMETRY IN TRACE ANALYSIS

Figure 13 Concentration profiles over time for selected masses (78, 128, 170, 178). Selection was performed using time windows within the time-of-flight mass spectrum. Instability in combustion between 350 and 450 s and the occurrence of a malfunction between 500 and 800 s are indicated by the variations in masses 78 and 128. Both of the larger masses show significantly different behavior.

In Figure 14, the same situation is shown for different species (besides naphthalene) and using the optimum sensitivity setting of the data acquisition system. It should be noted that the concentration scale is now calibrated and shows quantitative values for the concentrations. The spectrum for naphthalene is magnified (ppt) and in this form reveals a slight increase in concentration by about 100 ppt at 200 s. This means that the transition from combustion to gasification started considerably earlier. The three peaks obviously indicate a significant degree of instability in the combustion condition before a serious malfunction occurred. While benzene and naphthalene behave similarly to each other, obviously the fluctuations in fluorene, dibenzofuran, and alkyl-naphthalenes also show common features, although their relative concentrations at between 500 and 700 s and between 700 and 900 s are different. However, the remarkable fluctuation frequency, with a time constant of 30 s, indicates correlated processes of formation. A totally different process seems to be responsible for the formation of phenanthrene and larger polycyclic aromatics.

This kind of time-resolved trace analysis may therefore (in addition to its application as a controlling tool for

Figure 14 Concentration profiles over time for selected masses (128, 166, 168) measured synchronously with those shown in Figure 13. The concentrations are calibrated (in ppt for naphthalene and ppb for fluorene and dibenzofuran). Masses 166 and 168 show similar, but not equal, variations compared with mass 170 given in Figure 13. Naphthalene (now on a significantly expanded concentration scale) exhibits variations in concentrations (in addition to those already mentioned in the caption of Figure 13) even before the elapse of 300 s within the 100 ppt range.
environmental protection) be of help in understanding complicated combustion processes. The development of motors emitting less pollutants or of plants based on combustion processes is at least as important as emission control carried out on such motors and plants. In both cases, adequate (i.e. fast, selective, and sufficiently sensitive) analytical tools are required.

4.4 Application to Further Analytical Problems

Resonant laser-MS is usable in many other fields of application than just those of combustion processes. Three of these are presented in the following subsections.

4.4.1 Food Processing

The possibility of carrying out rapid controls would represent a very interesting, but often not yet feasible, option for the food processing industry. For example, the degree of roasting determines the quality and character of coffee. Many compounds which are responsible for the aroma of coffee are formed during the roasting process, while others already exist in the coffee bean. These compounds are subject to very different temporal changes in their concentrations. The ability to control their relative concentrations would supply an excellent means of regulating the roasting process on-line. This has been experimentally tested using resonant laser-MS, in a model roasting arrangement, with very promising success.\cite{175}

4.4.2 Gas Chromatography Coupling

The use of resonant laser-MS also opens up new possibilities for GC (as reported in section 3), giving rise to a three-dimensional technique. The combination GC and TOFMS has great advantages, since both techniques rely on selection by means of time. Gas pulses of species separated in time by the GC capillary can be mass analyzed with a high time resolution in the time-of-flight instrument. Species of different mass which have not yet been resolved by GC can then be discriminated. Species-selective ionization even allows one to distinguish between species of the same mass which are not separated by GC.

An example is shown in Figure 15. A gas chromatogram of the gas phase above a gasoline sample is shown. The coupling of the GC capillary and a supersonic beam valve provided the possibility of isomer selection. A fairly short, medium-resolution GC capillary was

![Figure 15](https://example.com/figure15.png)

**Figure 15** Detection of alkylated benzenes emitted from a gasoline sample by means of a combination of GC and resonant laser-MS. The spectrum shows the GC signal as a function of GC retention time, detected by means of semiselective ionization at 266 nm and a linear time-of-flight mass analyzer. During the GC run, a time window was transferred from mass 92 to 106, 120 and 134. The possibly present isomers with these masses (1 x at 92, 4 x at 106, 7 x at 120, and 15 x at 134) are displayed at the top of the figure. The GC capillary used cannot, however, separate all of these isomers, e.g. m- and p-xylene (the highest of the m = 106 peaks). Inset: selective ionization allows for further discrimination of isomers. At the laser wavelength 272.32 nm, only p-xylene was ionized and this appears in the m = 106 mass window; the other isomers ethylbenzene and, m- and o-xylene have been suppressed.
used, thus providing short retention times. During the GC run, time-of-flight mass spectra were continuously measured and the signal within a preset time window was recorded. This time window was shifted during the scan from mass 92 to mass 106, 120 and 134. An ionizing laser wavelength of 266 nm was used, resulting in semiselective ionization of aromatic molecules. As a result, a well-structured gas chromatogram is obtained from a very complex multi-component gas sample. The combination of all three methodical components (GC, REMPI, and TOFMS) obviously results in a selective, but still reasonably fast and sensitive device, requiring only low levels of effort for chemical sample preparation (these being significantly reduced for a fast, low-resolution GC capillary). To demonstrate the high level of selectivity achieved (e.g. for discrimination of the different isomers with mass 106: ethylbenzene and \(o\), \(m\), and \(p\)-xylene) with this instrumental set-up, ionization was performed with a semiselective (266 nm) and an isomer-selective wavelength (272.34 nm). The results are presented in the inset in Figure 15. \(p\)-Xylene is obviously selectively ionized at 272.34 nm, and at a mass of 106 it is the only sample component recorded out of the whole, unprepared gas sample.

4.4.3 Laser Desorption Coupling

Up to now, only gaseous samples have been considered. In many situations, however, samples in the condensed phase have to be analyzed for pollutants. If the sample is solid, laser vaporization (desorption of neutrals) may be the connecting element between solid sample and the gas phase necessary for mass spectrometry. Many groups are working in this field (see section 3; one of the most active is the research group of Zenobi et al). Nevertheless, laser desorption resonant laser ionization mass spectrometry as a method of trace analysis of solids and surfaces is still in the developmental stage. To address just one important example of this, sparse experience only exists for such complicated types of sample as soil, and considerable research efforts are still necessary. The need for a fast, but nevertheless selective and sensitive tool for the analysis of soil is obvious, if one considers such cases where larger areas of polluted soil have to be monitored within a dense grid of testing points.

In Figure 16(a), a schematic diagram of a set-up for the combination of laser desorption of neutral molecules and resonant laser-MS is shown along with an exemplary mass spectrum. The probe consists of a rod which can be moved continuously by a motor and gear assembly. The top of this rod is placed very near (\(\Delta x < 1\) mm) to the nozzle of the pulsed supersonic beam valve. A desorbing laser pulse is focused in this region. Neutral desorbed molecules are emitted into the supersonic beam, cooled by a large number of gas collisions and finally drift together with the gas pulse into the ion source.

Figure 16 (a) Experimental set-up for the coupling of neutral laser desorption of trace molecules from solid samples with resonant laser-MS. The sample is positioned within the top three centimeters of a continuously moved rod. (b) Mass spectrum (reflectron TOFMS) of laser-desorbed and laser-ionized (266 nm) dichloroanthracene. Note the low degree of fragmentation. (c) Mass region of the molecular ion displaying the \(^{12}\text{C}_6, ^{13}\text{C}_1\), as well as the \(^{35}\text{Cl}_6, ^{37}\text{Cl}_1\) and \(^{35}\text{Cl}_6, ^{37}\text{Cl}_1\) isotopomers.
where the resonant ionization takes place. Figure 16(b) shows the mass spectrum of laser-desorbed and laser-ionized (266 nm) dichloroanthracene. Figure 16(c) shows the molecular ion region displaying the different $^{13}$C and $^{37}$Cl isotopomers of this molecules in its natural isotopic mix.

5 FURTHER SPECIFICATIONS OF
RESONANT LASER MASS
SPECTROMETRY IN TRACE ANALYSIS

5.1 Calibration Methods and Detection Limits

Multiphoton processes are nonlinear optical processes. The ion yields are therefore correlated with laser intensities in a highly nonlinear way. This dependence changes when one of the single absorption steps becomes saturated at high laser intensities. In addition, fast intramolecular processes occurring in the excited intermediate molecular state may influence the ion yield and its dependence on laser intensity and pulse length. Even though this complicated behavior can be derived theoretically by rate equations, absolute ion yields cannot be predicted in a satisfactory way, since mostly single absorption cross-sections and intramolecular rate constants are not known. Quantification can be performed by measuring absolute cross-sections. The problem then is to transfer these results to the individual measurements (variations in gas density, laser intensity, focus geometry, charge density, etc.). Such measurements may help to estimate ion yields and thus also concentrations, but are usually not appropriate for reliable quantification.

An adequate calibration procedure is therefore important for analytical applications. For quantification, one can rely on the linear dependence of the REMPI–TOFMS signal on the concentration of a standard. This has been proven for many orders of magnitude down to the pptv concentration range. In general one may discriminate in quantification of analytical results by means of off-line comparison to an external calibration standard and quantification by on-line addition of an internal calibration standard. In the first case (off-line) an analyte standard can be used with a well-defined standard sampling. The standard signal is not disturbed by interfering mass peaks and the integrated peak intensity is well related to the concentration. However, external calibration standards can be used occasionally only. Long-term variations may be checked by means of external calibration before and after a measurement. In Figure 14, the external calibration method has been applied using ppb standards prepared dynamically with permeation and diffusion devices.

Using on-line calibration with an internal standard, the short-term variations produced by the instrument (e.g., laser intensity and spatial laser beam profile) can also be compensated for. This is performed either by adding a non-analyte calibration gas or by using a standard addition method with alternating measurement of the sample and of the sample with an additional standard. The first method permits the carrying out of rapid measurements resolving single shot-to-shot fluctuations, but the possible differences in the ionization yield of analyte and non-analyte molecules have to be considered. The second method uses an analyte standard; here, every second shot has to be used for calibration purposes. Shot-to-shot variations of the analyte signal or interfering substances may disturb the differential calibration.

All components which are available as standards may be quantified by these calibration and quantification techniques. For all other components the relative REMPI cross-sections between trace component and standard molecule have to be determined. These relative ionization yields are much more reliable than the quantitative ones (as mentioned above), if trace species and standard species are of similar molecular type. Measurements of relative cross-sections have been performed for a number of PAHs (naphthalene, biphenyl, acenaphthene, fluorene, phenanthrene, anthracene, fluoranthene, and pyrene) using GC/laser-MS at two different laser wavelengths. GC/laser-MS is well adapted to the problem of relative quantification, since it allows for introduction of a well-defined quantity of the sample molecule into the mass spectrometer at well-defined time intervals (widths of the GC peaks). A different method proposed for relative quantification involves laser desorption. Specially prepared thin polymer samples are used with homogeneous and well-defined trace concentrations. In response to a defined number of laser shots, holes (volume defined by laser focus and thickness of film) are ablated out of this thin film, which then releases well-defined quantities of trace molecules. Seventeen PAHs have been investigated by means of this method in the wavelength range 218–310 nm.

The detection limits of resonant laser-MS have been studied by several research groups, mostly employing supersonic molecular beams and tunable laser wavelengths. In the following, all detection limits refer to a signal-to-noise ratio of 1. Cool et al. have investigated the detection limits for numerous toxic combustion byproducts. Detection limits in the low-ppb (5 ppb for naphthalene at 302 nm; however, see comment below) and 10-ppt ranges (50 ppt for toluene at 267 nm) have been achieved for highly selective ionization of aromatic compounds using the first excited singlet state of the jet-cooled target molecules. With improved free-jet set-ups reducing the distance between nozzle and ionization...
region and using different, less selective REMPI transitions, detection limits in the low-ppt range have been reported.[111,114]

As for resonant laser-MS with an effusive molecular beam and fixed-frequency laser ionization (see Figures 7–14), sensitivity has been determined on the basis of a mass spectrum for a naphthalene permeation standard. A detection limit of 90 ppt has been achieved for naphthalene at 266 nm. This is more favorable than the results of Cool and et al. for naphthalene. The reason for this is not an intrinsically lower level of sensitivity in the supersonic beam arrangements (the example of toluene proves high sensitivity), but rather that 302 nm is an unfavorable ionization wavelength for (1 methyl group of xylene) can be selectively detected.

5.2 Specific Features of Resonant Laser Mass Spectrometry

In this last section, specific features and options of resonant laser-MS and also drawbacks will be discussed.

5.2.1 Compactness and Mobility

The laser mass spectrometers used for practical and realistic applications (e.g. analysis of combustion engine exhaust and municipal incinerator emissions) already had very reasonable dimensions of typically 1.20 m (length) × 1.00 m (width) × 1.20 m (height). The laser power supply and personal computer were located elsewhere (e.g. in the controlling room of the motor test facility). Both instruments were fitted with wheels; on one of the instruments hooks for lifting by crane and placing in special positions were even mounted. No time-consuming adjustment (in several cases even none at all) was necessary after transportation in a van for an entire day. For automobile exhaust analysis a commercially available instrument already exists; for incinerator measurements a prototype instrument has been developed at the Technical University, Munich.

5.2.2 No or Minimum Sample Preparation

For gas-phase analysis, no sample preparation or sample accumulation is necessary and thus real on-line measurement is possible. Of course, the gas inlet system has to be designed carefully to avoid memory effects. This is achieved by allowing for an overall heating temperature of the inlet system of 500–600 K. The efforts involved in the preparation of solid samples for laser desorption resonant laser-MS are mainly concerned with the physical consistency of the sample. A chemical separation of abundant or troublesome compounds is not necessary, since the level of selectivity of resonant laser-MS is already sufficiently good. For instance, high levels of water content, which can represent a serious problem in conventional analytical methods, or large concentrations of oxygen, which may lead to the burning out of electron-emitting wires, do not affect resonant laser ionization at all.

5.2.3 High Speed of Recording of Mass Spectra

The high speed achieved in connection with selectivity is one of the central features of resonant laser-MS. It is limited by the time characteristics of the gas inlet system and the repetition rate of the ionizing laser. A real time resolution of 20 ms is easily achievable (50 Hz lasers). However, in many cases a time resolution of 1 s is perfectly sufficient. This allows an averaging over 50 mass spectra per measurement (using 50 Hz lasers) and thus better reproducibility and signal-to-noise ratio.

5.2.4 High Selectivity

Owing to its two-dimensionality (wavelength and mass), the selectivity of resonant laser-MS is intrinsically good. Depending on the analytical problem to be dealt with, one can choose between an instrument with a good resolution (one or few fixed wavelengths and linear time-of-flight mass spectrometer) with reduced costs and dimensions and a very high-resolution instrument involving supersonic molecular beams, tunable lasers and reflectron mass analysis. In the first case, groups of molecular species (e.g. aromatics) can be discriminated from other species (mostly hydrocarbons) during the ionization process and detected mass selectively, by means of time-of-flight separation. In the second case, structural isomers (e.g. isobaric conformers of chlorinated aromatics) or even isotopeomers involving isotope substitution in chemically different positions (e.g. $^{13}$C in the aromatic ring or the methyl group of xylene) can be selectively detected.

5.2.5 High Sensitivity

The detection limit depends significantly on the type of multiphoton process and the cross-section absorption
processes involved. For most components detection can be achieved at least down to the ppm region, for many aromatics ppb sensitivity could be achieved even in very complex mixtures and in some experiments the ppt limit was even reached.

5.2.6 Applicable to Many Different Compounds

The range of different chemical compounds detectable by resonant laser-MS has been illustrated in studies of more than 25 representative gaseous components of the exhaust emissions from combustion engines,\(^{118}\) in which different wavelength ranges and multiphoton absorption and ionization schemes were investigated. These representative components include substances from different classes of chemicals, such as alkenes, carboxyls (in particular aldehydes), aromatic hydrocarbons, nitrogen and carbon oxides or catalytic converter products (e.g. HCN, NH\(_3\), H\(_2\)S, OCS). Additionally, the resonance-enhanced (and thus selective) MPI of innumerable individual chemical compounds has been successfully achieved and described in the literature (see section 3).

Of course, resonant laser-MS also has drawbacks. One of these is that particular species can only be ionized by REMPI with very low or diminishing efficiency. Another problem concerns the commercial availability of user-friendly large laser systems.

5.2.7 Ionization Yields?

One restriction on resonant laser ionization is the inavailability of tunable, easy to handle vacuum-UV laser sources. For this reason, molecules whose lowest excited electronic states lie far into the UV range (e.g. the alkanes) have to be ionized using multiphoton processes of higher order, which are less efficient. Furthermore, in some molecules resonant intermediate states are extremely short lived due to the occurrence of fast electronic relaxation or even dissociation. In these cases no molecular ion becomes visible in the mass spectrum. A typical example of this kind of behavior is to be found in nitroaromatics. Sometimes, the fragments (here NO) are nevertheless sufficient to permit discrimination and selective or partially selective detection. If not, other intermediate states or multiphoton processes have to be selected or ultrafast laser pulses (femtosecond laser) can be used.\(^{119–122}\) These solutions tend to be expensive or complicate the whole analytical method. In addition, selectivity may be reduced considerably. An alternative, less expensive approach could be provided by the combination using a short GC capillary for the separation of the problematic species without paying any attention to the separation from all other compounds. This is achieved by resonant laser-MS.\(^{135}\)

5.2.8 Customer-friendly Laser Systems?

Large pulsed laser systems in general, and lasers with tunable wavelength in particular, are still not well accepted by industrial users. In particular, pulsed, tunable lasers have not yet reached a state of development which permits them to be handled in an uncomplicated and convenient way. This is, however, more a question of supply and demand than one of technical state-of-the-art. The consequence of this is that high-resolution instruments with isomer selectivity may not get beyond a prototype stage in the near future. Resonant laser-MS instruments with reduced performance (i.e. few or even only one fixed laser wavelength) can be and have indeed already been commercialized. Even additional options such as high mass resolution achieved with reflectron mass spectrometry or additional selectivity achieved by coupling with a GC capillary could be incorporated in such commercial instruments to permit fast trace analysis.

ACKNOWLEDGMENTS

The examples presented here received the support of the German Ministry for Education, Science, Research and Technology (BMBF), the German automobile industry (FVV), and the Fonds der Chemischen Industrie (FCI). The authors would like to thank Prof. E.W. Schlag (TU Munich) and Prof. A. Kettrup (GSF Oberschleissheim) for their continuous interest and support in relation to many projects reported on in this article. We are indebted to Prof. M. Beckmann and Dr H. Griebel (both from the CUTEC Institut Clausthal Zellerfeld), to Dr Thiel and Dr Fröhntenicht (both BMW AG), to Prof. H.E. Rikeit (Mercedes Benz AG), and to Dr Franzen and Dr R. Frey (both from Bruker Franzen Analytik GmbH) for many fruitful discussions and opportunities to perform resonant laser-MS analysis at industrial facilities.

In laser spectroscopy the interaction of light emitted from various types of laser sources—tunable or nontunable in their output frequency—with the atomic or molecular species of interest is used to probe the sample through a variety of spectral responses. In order to perform laser spectroscopy suitable laser sources must be selected which meet the requirements of the chosen spectroscopic method. This means that the laser has to provide radiation which is in the wavelength range of interest, has the appropriate emission characteristics (lineshape) and a suitable energy to perform the measurements. Further requirements are pulse length (milliseconds to femtoseconds or continuous wave), repetition rate and beam profile. Nowadays, laser radiation can be generated with most of the required parameters necessary for the respective spectroscopic application, either directly or by generating new radiation frequencies by frequency mixing of one or several laser beams in a nonlinear medium (gas, liquid, solid).

As an example, the most direct probe is absorption of laser radiation (LAS, laser absorption spectroscopy) by suitable spectroscopically allowed transitions in atoms or molecules which are known from conventional spectroscopic methods. The increase or decrease in the laser radiation transmitted through the sample is then a measure of the amount of substance probed in the sample which characteristically absorbs at the required wavelength.

Laser light scattering methods, elastic (Rayleigh scattering (RS)) or inelastic (spontaneous Raman scattering (SRS)), are other techniques to probe the medium. In the first method, which is nonspecies specific, the density of the medium can be interrogated, whereas the second is able to probe all species with Raman-active vibration–rotation transitions.

There are several advantages in using laser spectroscopy instead of conventional spectroscopic techniques using conventional thermal light sources. The spectral brightness of laser beams is many orders of magnitude higher than that of thermal radiation sources, which correspondingly increase the detection sensitivity of laser spectroscopic techniques. In addition, the small linewidth of the emitted radiation increases dramatically the spectral resolution such that minor details of the spectroscopic branch investigated can be resolved. This enables more quantitative interpretations of all parameters influencing the lineshape and intensity of the probed transition, and as such the physical and chemical environment of the probed species: temperature, pressure, velocity, chemical species and so on.

It makes laser spectroscopic techniques much more selective than conventional methods, which often are not able to separate closely spaced spectral features from different species. A third advantage of laser spectroscopic techniques is connected with the variable pulse duration and repetition frequency of lasers: the very short pulse lengths can be used successfully to probe the sample within time periods which are short compared to any other physical or chemical time development—flow, chemical reaction, pressure changes and so on. Finally, the small spatial regions which can be probed by focusing diffraction limited laser beams makes laser spectroscopic techniques ideally suited for applications where high spatial resolution is required. All these advantages of laser spectroscopy are beneficial when the various techniques are applied as a diagnostic tool in combustion processes: flames constitute a complex interaction of fast chemistry with flow fields and surfaces and, therefore, a detailed understanding of combustion events often needs in situ, species-specific optical diagnostics with high spatial and temporal resolution.

In many applications laser spectroscopy is a developed technique and can even be applied by untrained people. However, numerous laser spectroscopic techniques require detailed theoretical knowledge of the spectroscopy underlying the respective technique, and use sophisticated equipment in order to obtain meaningful results. Future development is aimed towards simplifying experimental set-ups, data evaluation and maintenance. This development runs parallel to the breathtaking development in laser technology.
1 INTRODUCTION

Combustion is the oldest and one of the most successful technologies of humanity. An early important spectroscopic observation in a combustion process was made in 1859 by Robert Wilhelm Bunsen and Gustav Robert Kirchhoff, who recognized the origin of some of the famous dark lines in the solar spectrum first seen by Wollaston and indexed in 1814 by Josef Fraunhofer. Bunsen and Kirchhoff realized that it could not happen by chance that 60 of the Fraunhofer lines coincided with sixty iron emission lines measured in the hot nonluminous flame gases of the Bunsen burner. Their experimental success, however, was based on the ideas of Isaac Newton, who introduced the word spectrum into physics. After Bunsen and Kirchhoff, spectroscopy in flames became a rapidly growing field. However, the meaning of all the observed lines was not known until 1913 when Niels Bohr formulated his model of the atom. A few years later, Albert Einstein published his famous paper *Zur Quantenlehre der Strahlung* in which he derived Planck’s law and Bohr’s rule by discussing the possible elementary process of energy and momentum exchange through radiation. Despite Einstein’s clear description of the stimulated emission, the practical application of this principle was achieved only many years later in 1955, first in the microwave region (microwave amplification by stimulated emission of radiation (MASER)) and in 1960, in the visible spectral region (light amplification by stimulated emission of radiation (LASER)). The principle of stimulated emission has now been realized in all states of matter: solids, liquids, gases and free electrons. This allows generation of coherent radiation from the far-infrared to the X-ray region. Compared to flame spectroscopy with conventional light sources, the introduction of tunable lasers and the development of nonlinear optical techniques greatly expanded the potential of combustion spectroscopy. Now the spectroscopic states of atoms and molecules in combustion process can be observed nonintrusively with high temporal, spectral and spatial resolution. An excellent overview can be found in the book by Eckbreth.

Technical combustion processes consist of a complex multidimensional and time-dependent interaction of a large number of elementary chemical reactions with different transport processes for mass, momentum and energy. To increase the rate of chemical conversion, mostly turbulent flow conditions are applied in technical combustion. Similar to the laminar case, turbulent reactive flows can be described by solving the conservation equations for total species mass, momentum and enthalpy (Navier–Stokes equations). However, solving the Navier–Stokes equations by direct numerical simulation (DNS) is, even in the days of modern parallel computing a very demanding task. For a realistic system of liquid hydrocarbon oxidation in an internal combustion (IC) engine one would need more than $10^{21}$ computing steps. Therefore, at present and for the near future a DNS of three-dimensional turbulent reactive flows in technical combustion systems will not be possible. Instead, turbulence has to be modeled by the use of averaged Navier–Stokes equations, while mean reaction rates can be evaluated with the help of probability density functions (PDFs). These models can then be validated by multidimensional nonintrusive laser spectroscopic measurements. In addition, such laser spectroscopic techniques can be applied directly in technical combustion systems to study details of the complex interaction of chemical kinetics and transport processes and act as sensors for species concentration, temperature, flow and other parameters in active control loops to improve fuel efficiency and reduce the environmental effects of combustion.

2 BASIC PRINCIPLES

Laser-based combustion diagnostics as well as other optical diagnostic methods exploits extensively the direct interaction of light and matter, providing an important tool to observe the spectroscopic states of molecules and atoms with high spectral and spatial resolution in time regimes from hours to the femtosecond ($10^{-15}$ s) scale, using optical power densities from femtowatts ($10^{-12}$) to multiterawatts ($10^{12}$) per square centimeter. A main feature of optical techniques is the nonintrusive in situ investigation of the sample without any interference between the sample and the measuring device itself. This is especially important for reactive and aggressive environments like combustion processes where probe sampling techniques are of questionable value. In all cases light with a certain intensity and temporal and spectral distribution is sent onto or through a sample. The energy, in most cases in form of light, re-emitted from the interaction region of the irradiated sample is observed and used to characterize the composition and/or structure of the sample. This is done by a detailed analysis of the intensity, spectral composition or angular and temporal distribution of the scattered light. Only absorption techniques determine the losses of the incoming light along the line of sight.

2.1 Linear Techniques

A spectroscopic technique is called linear if the photometric effect shows a linear relationship to the amount of photons to which the sample is exposed. This is the case as long as the population of the initial state, mostly
Apart from this, LAS is able to determine simultaneously or molecular species which are present in a mixture. The subject of interest in LAS is mostly the absolute concentration or absorber density of one or more atomic or molecular species which are present in a mixture. Absorption spectroscopy is one of the oldest techniques for the most important linear techniques used for combustion diagnostics: LAS, laser-induced fluorescence (LIF), RS and SRS. 

2.1.1 Laser Absorption Spectroscopy

Absorption spectroscopy is one of the oldest techniques for the nonintrusive investigation of gaseous media. The subject of interest in LAS is mostly the absolute concentration or absorber density of one or more atomic or molecular species which are present in a mixture. Apart from this, LAS is able to determine simultaneously the physical boundary conditions (such as temperature, velocity, pressure or mass flux etc.) to which the absorbers are exposed.\(^{(11)}\)

The basic set-up of an absorption spectrometer can be described as a radiation source, which emits collimated light with an initial intensity \(I_0(v)\) through the sample under investigation towards a radiation detector. Part of the radiation, \(dI(v)\), is absorbed by atomic or molecular constituents along each path increment \(dl\) in a simple one step process. The light intensity \(I(v)\) behind the sample is monitored to determine the total loss and used as a quantitative measure of the number of absorbers along the beam path. The transition frequency \(v\) at which the absorption occurs is characteristic of the absorbing substance, so that a simultaneous species identification is possible (spectral fingerprint). Integration of the light losses over the total absorption path \(l\) leads, under the assumption of a homogeneous absorber distribution and a monochromatic light source, to the Lambert–Beer Equation (1)

\[
I(v, l) = I_0(v) \exp[-\kappa(v)\text{conc. } l] \tag{1}
\]

where \text{conc.} is the absorber concentration, and \(\kappa(v)\) the linear absorption coefficient (in the respective concentration units).\(^{(6,9)}\)

At thermal equilibrium the fractional population \(f_b(j, T)\) of level \(j\) with energy \(E_j\) is described by the Boltzmann Equation (2)

\[
f_b(j, T) = \frac{N_j}{N} = \frac{g_j}{Q(T)} \exp\left(\frac{-E_j}{k_BT}\right) \tag{2}
\]

where \(N\) is the total number density (cm\(^{-3}\)) of species, \(g_j\) is the statistical weight of level \(j\), which is closely related to the total angular momentum quantum number \(j\), \(T\) is the temperature, \(k_B\) is Boltzmann’s constant, and \(Q(T)\) is the partition function. Under equilibrium of particle ensemble and radiation field the upward and downward radiative transition rates have to be equal and the Einstein coefficients are related by Equation (3):

\[
\frac{A_{21}}{B_{21}} = \frac{8\pi \hbar v_{12}^3}{c^3} \tag{3}
\]

At low laser intensity the total amount \(\Delta I\) absorbed at the transition frequency \(v_{12}\) by any upward transitions from \(E_1\) to \(E_2\) is then described as, Equation (4):

\[
-\Delta I(v_{12}) = I_0(v_{12})N_1\Delta\lambda \frac{A_{21}c^2}{8\pi v_{12}^3} \tag{4}
\]

2.1.1.1 Absorption Line Parameters: Line Strength and Shape

In order to remove its lineshape dependence \(\kappa(v)\) is often expressed as a product of a frequency independent line strength factor \(S\), called integrated absorption coefficient, and a normalized lineshape function.

Figure 1 Energy level diagrams showing photon–species interaction (left) and schematic experimental set-up (right) for linear laser–spectroscopic techniques discussed in the text. \(\omega_i = 2\pi\nu_i\), circular frequency of respective incident and/or emitted radiation; \(N_i\), number density (cm\(^{-3}\)) of \(i\)th energy level; \(Q\), \(P\), quenching, predissociation rate (s\(^{-1}\)), respectively. Solid arrows indicate radiation- or collision-induced processes, and wavy arrows incident/ emitted radiation, respectively.

Laser absorption spectroscopy (LAS)

\[
\omega_l \rightarrow N_2 \rightarrow N_1 \quad \text{with} \quad L
\]

Laser induced fluorescence (LIF)

\[
\omega_l \rightarrow \omega_{FL} \rightarrow Q \rightarrow \omega_F \quad \text{with} \quad F
\]

Rayleigh scattering (RS)

\[
\omega_l \rightarrow \omega_{RS} \quad \text{with} \quad R
\]

Spontaneous Raman scattering (SRS)

\[
\omega_l \rightarrow \omega_{SR} \quad \text{with} \quad S
\]
\( \phi(v - v_{12}) \) with half width \( \gamma \) centered at \( v_{12} \), Equation (5):

\[
\kappa(v) = S\phi(v - v_{12}), \quad \int_{-\infty}^{\infty} \phi(v - v_{12}) \, dv = 1
\]

\[
S = \int_{-\infty}^{\infty} \kappa(v) \, dv
\]  

With these relations we can rewrite the Lambert–Beer relation as Equation (6)

\[
I(v, l) = I_0(v) \exp[-S'\phi(v)N_1l] \quad \text{with} \quad S' = \frac{S}{N_1}
\]  

and remove the lineshape dependence by integrating over the entire absorption line, so that the total spectral “area” \( S \), occupied by the absorption line, reflects only the absorption strength and the number density of absorbers in the initial level \( E_1 \). In this case the relation between the Einstein coefficient for spontaneous emission, \( A \), temperature, if the pressure remains constant during the transition. In the first case almost any heteronuclear molecule relevant to combustion like \( \text{H}_2\text{O}, \text{CO}, \text{CO}_2, \text{CH}_4, \text{NO}, \text{NO}_2, \text{NH}_3 \) and so on can be detected via strong ground state rotational–vibrational transitions in the mid-infrared or via weaker overtone and combination bands in the near-infrared (0.75–3 \( \mu \)m) spectral region. Even stronger electronic transitions of all atoms, ions, molecules and free radicals, e.g. \( \text{H}, \text{O}, \text{N}, \text{O}_2, \text{NO}, \text{CH}_4, \text{OH}, \text{NH}_3, \text{H}_2 \text{O}, \text{H}_2 \text{O}_2 \) important in combustion are accessible in the visible (350–750 nm) and most often in the ultraviolet (UV) part (<350 nm) of the spectrum.

2.1.1.2 Temperature Dependencies In any combustion-related sensor for molecular species it is very important to recognize that \( S \) is a strong function of temperature. If the pressure remains constant during the temperature change the absorber density will be modified by \( T^{-1} \). In addition, the fractional population \( f_B \) (Equation 2) at the initial energy level changes as a function of temperature and energy of the probed state. A change in temperature of several hundred degrees can cause variations in the integrated absorption coefficient over two orders of magnitude. On the other hand, this strong temperature dependence can be used to measure the temperature itself by rationing the integrated absorption of two suitable transitions.\(^{11,13}\)

2.1.1.3 Lineshapes and Broadening The finite lifetimes of all excited states lead to natural or radiative line broadening, which is described by a Lorentzian profile with a width \( \gamma_N \). In addition, the thermal motion of the absorbers with mass \( M \) in a gas in thermal equilibrium at temperature \( T \) causes a velocity dependent Doppler shift in transition frequency, resulting in a distribution of transition frequencies, which is modeled by a Gaussian lineshape function of width \( \gamma_D \). Furthermore, collisional broadening is generated by frequent perturbations of the absorber through collisions with other gas molecules, which results in a shortening of the lifetime of the excited state. This lineshape often is sufficiently described by a Lorentzian function. To take into account the effect of different collision partners, separate foreign-gas (\( \gamma_f \)) and self-broadening (\( \gamma_s \)) coefficients are introduced and empirical expressions for the pressure and temperature dependence of the total halfwidth are combined to give Equation (7)

\[
\gamma_{\text{Lorentz}} = \gamma_s + \gamma_f \frac{p_t}{p_{\text{tot}}} \left( \frac{T_0}{T} \right)^n
\]  

with \( T_0 \) a reference and \( T \) the actual temperature, and \( p_s, \ p_t \) the partial pressures of the absorber and the perturber species and \( p_{\text{tot}} \) the total pressure respectively. \( n \) reflects the temperature dependence and from kinetic gas theory is a power law with \( n = 0.5 \). Finally, at intermediate pressures, when none of the above mentioned mechanisms dominates, the experimental lineshape is described by a convolution of Gauss and Lorentz profiles, the so-called Voigt function, which generally cannot be expressed in an analytical form. Approximations and further literature on lineshapes are accessible through.\(^{9,12,14}\)

LAS can be applied to any absorber which has either a permanent dipole moment or an allowed electronic transition. In the first case almost any heteronuclear molecule relevant to combustion like \( \text{H}_2\text{O}, \text{CO}, \text{CO}_2, \text{CH}_4, \text{NO}, \text{NO}_2, \text{NH}_3 \) and so on can be detected via strong ground state rotational–vibrational transitions in the mid-infrared or via weaker overtone and combination bands in the near-infrared (0.75–3 \( \mu \)m) spectral region. Even stronger electronic transitions of all atoms, ions, molecules and free radicals, e.g. \( \text{H}, \text{O}, \text{N}, \text{O}_2, \text{NO}, \text{CH}_4, \text{CH}, \text{OH}, \text{NH}_3, \text{H}_2 \text{O}, \text{H}_2 \text{O}_2 \) important in combustion are accessible in the visible (350–750 nm) and most often in the ultraviolet (UV) part (<350 nm) of the spectrum.

2.1.1.4 Long-path Absorption Techniques To increase detection sensitivities in absorption measurements the pathlength of the sample traversing beam has to be maximized. White- or Herriot-type mirror arrangements often are employed at the cost of spatial resolution. Another line-of-sight absorption technique which has emerged recently as a species-specific combustion diagnostic tool to monitor reactants, intermediates and products with very high sensitivity (<10\(^{-6}\) fractional absorption) is cavity ring-down laser absorption spectroscopy (CRLAS).\(^{19}\) In CRLAS a laser beam is coupled into a linear cavity formed by two concave mirrors with high reflectivity (>99.98\%). The intensity decay in the cavity is given by \( dI/dt = -MTtc/L \), where \( L \) is the length of the cavity with mirrors of transmissivity \( MTc \). This leads to the exponential solution \( I = I_0 \exp(-MTtc/L) \) with the decay constant \( \tau = L/MTc. \) One can define a total round trip loss of \( \Gamma = 1 - \exp[-2L/c\tau] \), since the round trip time in the cavity is \( \tau_{\text{TR}} = 2L/c \).\(^{19}\) The intensity of the trapped light pulse is monitored in time via transmission through the output mirror on successive passes inside the cavity. Any absorption generated by the probed species increases the overall photon decay rate of the light pulse.
LASER-BASED COMBUSTION DIAGNOSTICS

in its multiple travels between the mirrors (Equation 8)

\[
\frac{1}{\tau} = \frac{(MT + \Lambda + \sigma(\lambda)n)\varepsilon}{L}
\]

from that of the empty resonator with \(\tau_{RT}\). In Equation (8) \(MT + \Lambda\) are cavity losses caused by mirror transmission \((MT)\), and nonspecific absorption and scattering \((\Lambda)\); \(\sigma(\lambda)\) is the absorption cross-section at wavelength \(\lambda\) of the sample (concentration \(n\)) placed inside the cavity. Therefore, the decay time is a quantitative measure of the absorption strength and hence the concentration of the species. Since only the decay time is relevant the method also has the advantage of being insensitive to pulse-to-pulse energy fluctuations of the laser source. However, any other intensity losses should be avoided (scattering, surface reflection, bulk material absorption etc.), which reduce the beam intensity inside the cavity, thereby reducing the decay time.

Intermediates in hydrocarbon combustion, such as hydroxy, methylene and methyl radicals, have been detected in laminar flames\(^{20,21}\) and low pressure plasmas\(^{22}\) respectively, using CRLAS or intracavity laser absorption spectroscopy (ICLAS) with UV light to stimulate electronic transitions. The exceptionally high signal-to-noise level in such measurements leads to very accurate, path-integrated temperature determinations of less than 2\% in atmospheric pressure flames. Using CRLAS, HCO\(^{23}\), hydrocarbons (CH\(_4\), CH\(_3\)), water and CO\(_2\) were also recently detected quantitatively in their characteristic infrared spectrum around 3 \(\mu\)m with very high spectral resolution (0.007 cm\(^{-1}\)) in low pressure (35 torr) laminar methane/air flames using an optical parametric oscillator (OPO)\(^{24}\) and ICLAS has made possible the detection of CH\(_2\) in flames\(^{21}\). Apart from combustion diagnostics CRLAS is increasingly being applied in other fields of physical chemistry including high resolution spectroscopy\(^{25}\) and chemical kinetics\(^{26}\).

2.1.2 Laser-induced Fluorescence

LIF is the process of spontaneous emission from an excited electronic state populated upon absorption of a laser photon. Large cross-sections mainly in the visible and UV spectral range are generally observed for electronic transitions. The exceptionally high cross-sections mainly in the visible and UV spectral range enable species detection down to the sub-parts per million range. Many combustion-relevant species like OH, O\(_2\), NO, CH, CN, NH, C\(_2\) can be accessed selectively (Eckbreth\(^7\) and references therein). In many cases this technique is easily extended to two-dimensional imaging yielding concentration measurements with high spatial resolution simultaneously with high temporal resolution upon nanosecond laser pulse excitation.

2.1.2.1 Linear Laser-induced Fluorescence

Equation (9) describes the LIF intensity \(I_{\text{LIF}}\) in the linear range for one species as

\[
I_{\text{LIF}} = N(p, T)f_B V B_{jk} A_{ik} g_j(p, T) \phi \eta \frac{\Omega}{4\pi}
\]  

The LIF intensity is proportional to the number density \(N(p, T)\) of the excitable molecules in the probed volume \(V\) which is determined by \(N(p, T)\) times the temperature-dependent Boltzmann fraction \(f_B\) giving the population of the initial level \(i\). The Einstein \(B_{jk}\) coefficient describes the absorption probability for transition \(i \rightarrow k\). The fluorescence intensity depends linearly on the laser intensity \(I_L\) and the spectral overlap \(g_j(p, T)\) of the laser profile and the absorption line. All these factors determine the number density of excited molecules and, therefore, the absorption part of the LIF process. The fluorescence quantum yield \(\phi\) in Equation (10) gives the ratio of the spontaneous emission rate (from level \(k\)) versus the total rate of (radiative and nonradiative) relaxation processes:

\[
\phi = \sum_j \frac{A_{ki}}{A_{jk} + Q_j(p) + P_k}
\]  

\(\phi\) therefore depends on the Einstein \(A_{ki}\) coefficient for spontaneous emission divided by the sum of the rates of all deactivation processes of the excited state (spontaneous emission from state \(k\) to all possible ground state levels: \(A_{ki}\), quenching \(Q_j(p)\) and predissociation \(P_k\)). The detection efficiency of fluorescence photons depends on the observed solid angle \(\Omega/4\pi\), the transmission of the optical system \(\varepsilon\) and the response of the detector \(\eta\). Effects of polarization are discussed by Rothe et al.\(^{27}\)

When quantifying signal intensities obtained from linear LIF one usually has to account for the temperature-dependent population of the ground state \(f_B\) and the temperature- and pressure-dependent spectral overlap \(g_j\). Furthermore, at atmospheric pressure and above (for nonpredissociative states, see below) the fluorescence quantum yield \(\phi\) is strongly influenced by the quenching rate \(Q_j\) which depends on temperature, pressure and local gas composition. The temperature dependence of the ground-state population can be minimized by choosing a transition with minimized temperature sensitivity in the expected temperature range. The spectral overlap factor can be calculated from spectra simulations which are available for the most important combustion relevant species.\(^{28,29}\) This is mainly important in high pressure applications where collision broadening causes the individual rotational lines to blend giving absorption features which are spectrally broader than the laser line. At atmospheric pressure and above, the denominator in the fluorescence quantum yield \(\phi\) (see Equation 9) is dominated by fluorescence quenching \((Q \gg A)\) and may introduce large uncertainties when not corrected for.
2.1.2.2 Saturated Laser-induced Fluorescence

In the fully saturated regime the population of the excited level reaches steady state and depends only on the ratio of the probabilities of stimulated absorption and emission \((B_{12}/B_{21})\). The influence of other depopulation processes of the excited state like collisional quenching disappears and the fluorescence intensity \(I_{\text{LIF}}\) is described according to Equation (11):

\[
I_{\text{LIF}} = N(p, T) f_b V \frac{B_{ki} A_{ik}}{B_{ki} + B_{ik}} \Omega \frac{\eta}{4\pi} \tag{11}
\]

Therefore, the fluorescence intensity only depends on the number of excitable molecules \(N_{\text{fb}}\) \(V\), on molecular constants and on the detection probability defined by the experimental set-up. From the two-level assumption saturation is reached at the saturation spectral irradiance \(I_{\text{sat}}\) (Equation 12), which at atmospheric pressure is in the range of \(1.3 \times 10^6 \text{ W cm}^{-2} \text{cm}^{-2}\) for OH and \(1.2 \times 10^6 \text{ W cm}^{-1} \text{cm}^{-1}\) for NO (see references in Eckbreth\(^7\)):

\[
I_{\text{sat}} = \frac{(A_{21} + Q_{21})c}{B_{12} + B_{21}} \tag{12}
\]

Experimentally however, full saturation is not easy to obtain since both temporal and spatial contributions from nonsaturated LIF have to be excluded from signal detection. With very short detection times excluding the beginning and the end of the laser pulse, and referencing of LIF acquired along two different optical paths simultaneously (two-optical path laser-induced fluorescence\(^{30}\) (TOPLIF)), saturated LIF measurements are feasible.

2.1.2.3 Laser-induced Predissociative Fluorescence

Curve crossings of bound and dissociative states in the excited level cause a very short lifetime of the excited molecule. The predissociation rate is a molecular constant and, therefore, independent of pressure and colliding molecules. If choosing appropriate excited levels (i.e. OH A, \(v' = 3\) or O\(_2\) B-state) the denominator in the fluorescence quantum yield (Equation 10) is dominated by \(P\) with \(P \gg Q\). In this case, the quenching influence can be omitted leaving the fluorescence quantum yield independent of pressure and temperature. However, since \(Q\) is rising with the collision frequency, the pressure range where the assumption of LIPF (laser-induced predissociative fluorescence) applies is limited.

2.1.2.4 Computation of Quenching Rates

For a large number of colliders quenching rates for, e.g. OH and NO have been determined as a function of temperature and pressure enabling the development of simulation models.\(^{31,32}\) Therefore, quenching can be quantified as long as local gas composition and temperature are known.

However, close to the flame front where composition changes quite dramatically, because of transient species like atoms and radicals, concentration data are not available from experiment. Chemical kinetics simulations of laminar flames using full chemistry allow estimation of the influence of the transient species in the flame front. In the burned gas region, however, where concentrations are close to equilibrium and where transient species are absent, the database provided by the quenching models is good for correcting LIF intensity data.

2.1.2.5 Time-resolved Laser-induced Fluorescence

The fluorescence quantum yield \(\phi\) can also be expressed as a ratio of fluorescence lifetimes according to Equation (13)

\[
\phi = \frac{\tau_{\text{eff}}}{\tau_{\text{rad}}} \tag{13}
\]

where \(\tau_{\text{rad}}\) is the fluorescence lifetime related to the spontaneous emission rate only, \(\tau_{\text{eff}}\) is the effective fluorescence lifetime in the system under study, influenced by all depopulation processes. Therefore, with a measurement of \(\tau_{\text{eff}}\) the fluorescence quantum yield can be calculated and from Equation (9) concentration information can be gained without detailed knowledge about the depopulation processes of the excited state. In low-pressure systems this method is frequently applied since timescales are sufficiently long to use nanosecond lasers for excitation. At atmospheric pressure picosecond laser systems and ultrafast detectors have to be used.\(^{33,34}\)

When calculating quenching rates from time-dependent LIF measurements the simple two-level model must be expanded including neighboring rotational states which are populated via collision induced rotational energy transfer (RET) for both the ground state and the excited state. The two-level model is sufficient when either no RET is present or full thermalization over the complete level manifold can be assumed. For intermediate cases however, four-level models\(^7\) have been suggested allowing for time-dependent calculation of LIF signals.

2.1.2.6 Energy Transfer Processes

Besides fluorescence quenching which describes nonradiating transitions to the ground state, other collisionally induced energy transfer processes have to be considered. Electronic energy transfer (EET), vibrational energy transfer (VET) and RET populate excited levels which subsequently fluoresce. This especially gains importance if levels with significantly different fluorescence lifetimes are involved. Furthermore, the fluorescence signal may be shifted to different spectral regions compared to the direct transitions from the laser-populated level. The implications of these effects are discussed in further detail by Eckbreth and by Rothe et al.\(^7,27\)
2.1.2.7 Quantification of Laser-induced Fluorescence Signal Intensity

With all the considerations mentioned above, from Equations (9) or (11) semi-quantitative concentration data can be derived from LIF signal intensities. Quantification, however, requires knowledge of the detection efficiency \( n \Omega/4\pi \) determined by the detection system. These factors are usually obtained via calibration procedures. Different attempts at calibration have been applied using Raman or RS from a known number density in the probe volume with excitation and detection channels being exactly equal to the LIF measurements to correct for the visualized solid angles and detection efficiency of optics and detectors. However, to include transmission effects of filters used for detection it is advantageous to calibrate with the species that is to be measured. Therefore, calibration cells filled with known gas mixtures are applied for stable species. Transient species on the other hand can be calibrated by using standard flames where species concentrations and temperatures obtained, respectively, from absorption and CARS (coherent anti-Stokes Raman scattering) measurements are well documented for different operating conditions. In the case of NO, calibration is possible by seeding known quantities of NO to the flame under study. In stationary combustion, objects like laminar flames absorption measurements were carried out to assess absolute concentrations.

2.1.2.8 Laser-induced Fluorescence Thermometry

The temperature-dependent population of different ground state levels allows temperatures to be assessed by LIF. In stationary systems local temperatures can be obtained by detecting and simulating fluorescence excitation spectra, for example of NO. Choosing two transitions where the ground state levels have an appropriate energy difference \( (F_2 - F_1) \), two-color excitation provides a possibility for time-resolved temperature measurements which can be extended to two-dimensional temperature mapping. Temperature \( T \) is calculated according to Equation (14) from the fluorescence intensities \( I_{\text{LIF,1}} \) and \( I_{\text{LIF,2}} \) obtained upon excitation with the respective laser wavelengths:

\[
T = \frac{F_2 - F_1}{k_B [\ln(I_{\text{LIF,1}}/I_{\text{LIF,2}}) + c_{\text{calib}}]} \tag{14}
\]

\( k_B \) is the Boltzmann constant and \( c_{\text{calib}} \) is a constant obtained from independent calibration measurements. Ideally the excited levels populated upon excitation of either laser photon should be identical. In this case all depopulation processes in the excited state like RET and quenching are the same for both transitions and cancel out when calculating temperatures. Local concentration cancels out as well. However, saturation and ground state depopulation have to be considered very carefully to prevent large systematic errors. Two-line temperature measurements have been shown using OH, \( \text{O}_2 \), and NO. Another possibility for temperature measurement is provided by molecular tracers like ketones, which exhibit a shift in their absorption spectrum with temperature which can be used for two-line temperature measurements in inhomogeneously-mixed combustion systems. Single-line techniques give information about the local gas density which can be transferred to temperature when pressure and species concentration are known (and spatially invariant).

2.1.3 Rayleigh Scattering

RS takes advantage of the statistical density fluctuations in a polarizable medium. For an electromagnetic wave travelling in \( \gamma \)-direction with its \( \mathbf{E} \) vector linearly polarized in the \( \gamma \)-direction the induced dipole moments \( p \) are proportional to the electric field and to the respective tensor component of the polarizability \( a \) (of an assumed space fixed scattering molecule) which causes scattered light to be polarized in the \( \gamma \)- or \( z \)-direction when observed in the \( x \)-direction in Equation (15)

\[
p_x = \varepsilon_0 a_{\gamma z} E_z^2
\]

\[
p_z = \varepsilon_0 a_{\gamma z} E_z^2 \tag{15}
\]

The radiant intensity of scattered light into a unit solid angle perpendicular to the propagation direction of the incident light beam of an ensemble of arbitrarily oriented molecules is proportional to the square of the induced dipole moment, and can be written as (Equation 16)

\[
I_{\gamma z}^0 = \frac{\partial P(\pi/2)}{\partial \Omega} \propto \varepsilon_0^2 a_{\gamma z}^2 E_z^2 = \frac{1}{15} \gamma^2 E_z^2
\]

\[
I_{\gamma z}^2 = \frac{\partial P(\pi/2)}{\partial \Omega} \propto (a_{\gamma z})^2 E_z^2 = \frac{1}{45} (45a^2 + 4\gamma^2) E_z^2 \tag{16}
\]

where \( a \) and \( \gamma \) are the mean value and the anisotropy of the polarizability tensor. In a quantum mechanical derivation the harmonic oscillator approach for the oscillating charge leads to the \( \gamma^4 \)-dependence of the scattered radiant intensity (Equation 17):

\[
f_{nm}^\Omega = \frac{\pi^2}{2\varepsilon_0 c^3} (\psi_0 + \psi_{nm})^4 \rho_{nm}^2 N_1 \tag{17}
\]

with a proportionality to the number of species \( N_1 \), to the squared matrix element of the induced transition \( \rho_{nm} \) from state \( n \) to \( m \) and to the fourth power of the frequency of the exciting radiation \( \omega_0 \). For RS \( m = 1 \) and one arrives at Equation (18) for the scattered radiant power of the Rayleigh scattered light

\[
P_{RS} = P_L n \left( \frac{\partial \varepsilon}{\partial \Omega} \right)_{\text{mix}} \Omega \epsilon \tag{18}
\]
where $P_L$ is the incident laser power and $n$ the number density of scatterers in the probe volume sampled along a length $l$. The RS cross-section of the gas mixture can be calculated from the mole fractions $x_i$ of the individual species in the mixture (Equation 19):

$$\left(\frac{\partial \sigma}{\partial \Omega}\right)_{\text{mix}} = \sum_i x_i \left(\frac{\partial \sigma}{\partial \Omega}\right)_i$$

Therefore, from the Rayleigh intensity data the density in mixtures with known scattering cross-section and the temperature (and pressure for a known temperature) can be determined on a single shot basis in a one-(collimated laser beam) or two-(laser light sheet) dimensional area.

### 2.1.4 Spontaneous Raman Scattering

While many combustion species can be detected by single photon absorption techniques, there are important exceptions for species at major concentration levels (homonuclear molecules with singlet-ground states like H$_2$ and N$_2$), which have to be monitored by, for instance Raman spectroscopy or two-photon techniques. Since almost all molecular species exhibit Raman active vibrational modes, SRS has developed to the method of choice for the determination of major species concentrations in turbulent combustion processes. Although inherently a weak process (the ratio of the captured Raman signal intensity to the incoming laser intensity, $I_{\text{SRS}}/I_L$, amounts to approx. $10^{-14}$), and being susceptible to stray light, with high power KrF-, Nd : YAG- or dye lasers, pointwise or spatially resolved measurements along the laser beam axis are possible within a single exciting light pulse. The Raman radiant intensity in Equation (20) emitted from a single species for a Q-branch transition ($\Delta v = +1$, $\Delta J = 0$) into a small solid angle $\Omega$,

$$P_{\text{SRS}} = P_L \left(\frac{\partial \sigma}{\partial \Omega}\right)_{zz} \Omega e$$

$$I_{\text{SRS}} = \frac{hN(v_0 - v_{12})^4}{8mc^4[1 - \exp(hc\nu/kT)]} \left\{(a')^2 + \frac{4}{45}(\gamma')^2\right\} I_L$$

is determined by the differential Raman scattering cross-section, $(\partial \sigma/\partial \Omega)_{zz}$, the laser radiant power $P_L$ and the illuminated and imaged probe length $l$. In Equation (21) $a'$ and $\gamma'$ are the respective derivatives of $a$ and $\gamma$ with respect to the spatial coordinate of the Raman excited vibration. This enables mixture fractions to be readily determined from single pulse measurements.

### 2.1.5 Laser-induced Incandescence

The exploration of the potentials of laser spectroscopic techniques in sooting flames is much less advanced than in clean particulate-free environments. The possibility for absorption or scattering of laser radiation in penetrating combustion media makes diagnostic methods a challenge in fuel rich and sooting environments. One technique with great prospects for obtaining spatially resolved one- and two-dimensional imaging of soot distributions is laser-induced incandescence (LII). In this technique the soot particles are exposed to a high flux of radiation, usually from a fundamental or frequency doubled Nd : YAG laser beam, whose absorption leads to their strong heating with subsequent total evaporation and cooling. The time-resolved detection of the emitted blackbody radiation constitutes a quantitative measure of the soot volume fraction if an independent calibration by extinction was performed. In an elegant experimental set-up this calibration was done simultaneously with the LII signal generation by splitting the two-dimensional laser sheet into a low intensity part (for extinction) and a high intensity part (for LII). Both were sent through the same spatial region in the turbulent flame with a temporal separation of several nanoseconds and then the required images (2 for extinction, 1 for LII) were placed onto separate partitions of the CCD (charge coupled device) camera chip.

The detected LII signal is given by Equation (22)

$$I_{\text{LII}} = \int_{t_1}^{t_2} J(t, \lambda_{\text{em}}) \, dt$$

where $(t_2 - t_1)$ is the opening time of the intensifier gate of the CCD camera which is activated at time $t_1$ after the laser pulse. The temporal evolution of the soot particle size distribution function, $J(t, \lambda_{\text{em}})$, is dependent in a complicated manner on the chosen emission wavelength $\lambda_{\text{em}}$ in the Planck equation for the blackbody radiation flux $q_{\lambda}$ through the conductive heat loss and radiation balance of the superheated particle. Through analysis of the temporal profile of the LII signal intensity the particle size can be deduced as an important parameter in the history of particle growth in the flame.

### 2.2 Nonlinear Techniques

Nonlinear wave mixing phenomena usually are not observed at the low light intensities of incoherent thermal radiators. However, the development of high-power tunable laser systems has triggered the study of numerous new nonlinear optical phenomena in liquid, solid and gaseous samples. The attained signal intensities in molecule specific resonantly enhanced higher order wave mixing processes can be large due to their strong dependence on the intensities of all incoming beams, the concentration of the sample molecule and the interaction length (e.g. the effective spatial extent in the sample where the signal is produced inside the
Coherent anti-Stokes Raman scattering (CARS)
\[ \omega_{\text{CARS}} = 2\omega_1 - \omega_2 \]

Degenerate four wave mixing (DFWM)
\[ \omega_{\text{DFWM}} = 2\omega_1 - \omega_1 \]

Polarization spectroscopy (PS)
\[ \omega_{\text{PS}} = 2\omega_1 - \omega_1 \]

Sum frequency generation (SFG)
\[ \omega_{\text{SFG}} = \omega_{\text{vis}} + \omega_{\text{IR}} \]

Resonance enhanced multiphoton ionization (REMPI)
\[ n_{\text{on}} + n_{\text{on}} > n_{\text{on}} \]

Figure 2 Energy level diagrams showing photon–molecule interaction (left) and schematic experimental set-up (right) for nonlinear laser spectroscopic techniques discussed in the text. See Figure 1 caption for more detail.

interaction region of all beams). The energy level schemes of multibeam techniques most often established in combustion diagnostics today are summarized in Figure 2 together with the sketched experimental set-ups. The nonlinear susceptibilities are enhanced whenever one or more of the frequencies of the interacting laser beams coincide with allowed one- or multiphoton transitions. In the macroscopic picture the induced higher order polarization terms arise from the nonlinear mixing of the input waves and give rise to the radiation of the same or various new sum and/or difference frequency combinations of the frequencies of the input waves. This produces a coherent signal beam in a direction determined by the phase matching condition, Equation (23)

\[ \vec{k}_{\text{sig}} = \sum \vec{k}_j \]  

where \( |\vec{k}_j| = n_j \omega_j / c \), is the magnitude of the respective beam wave vector. Through focusing of the beams good spatial resolution transverse to the beam propagation direction can be obtained with sample volumes of several cubic micrometers without sacrifice of signal intensity loss due to larger crossing angles.

2.2.1 Coherent Anti-Stokes Raman Scattering

Among the coherent Raman processes CARS is almost exclusively being used in practical combustion diagnostics. In CARS experiments (compare Figure 2) one fixed frequency (pump) and one broadband (Stokes) laser beam in the visible region with their frequency difference equal to a Raman allowed transition are aligned and focused into the sample to create, in a four-wave mixing process, a coherent beam at the anti-Stokes frequency \( 2(\omega_1 - \omega_2) \), well-separated spatially and spectrally from all incoming beams. The CARS radiation then is dispersed in a spectrometer and detected with a CCD camera (Figure 3). In the nonsaturated regime the CARS intensity at frequency \( \omega_{\text{CARS}} = \omega_3 = 2\omega_1 - \omega_2 \) for an isolated transition \(^5\) in Equation (24)

\[ I_{\text{CARS}} = I_3 = \frac{\omega_3^2}{\eta_1^2 N_2^2 c^4 \epsilon_0^2} (\Delta \epsilon)^2 I_2 |x_{\text{CARS}}^{(3)}|^2 \]

with \( x_{\text{CARS}}^{(3)} = K_j \frac{\Gamma_j}{2 \Delta \omega_j - i \Gamma_j} + x_{\text{nr}} \)

\[ K_j = \frac{\omega_3^2 (4\pi)^2 n_1 \epsilon_0 c^4}{n_2^2 \omega_j^2 \Gamma_j} \frac{\partial \sigma}{\partial \Omega} j \]

is dependent on higher powers of the pump (\( I_1 \)) and Stokes (\( I_2 \)) laser intensities as well as on the square of the number density difference \( N \Delta \epsilon \) between lower and upper Raman level of the \( j \)th transition. Equation (24) is written for perfect phase matching of the beams, i.e. when Equation (23) holds and the corresponding signal intensity is maximized. \( \Gamma_j \) is the total broadening rate of the transition and \( \Delta \omega_j = \omega_1 - \omega_2 - \omega_j \) the detuning from the Raman transition frequency. The spectral structure of the CARS signature over thermally populated levels is contained in the expression of the third-order susceptibility \( x_{\text{CARS}}^{(3)} \) (Equation 25), which, therefore, is an accurate measure of the gas temperature. This is exploited for thermometry applications through least squares fitting of computer generated to experimental CARS spectral shapes, if proper account is taken of the various physical effects contributing to the CARS spectral signature, such as coherences in the CARS pump beams \(^{36,37} \) saturation and collisional effects \(^{38,59} \) or the noise characteristics when broadband Stokes lasers are employed.\(^{60} \)
made in the single shot broadband rotational-CARS technique.\textsuperscript{(65,66)} The dicyanomethylene-2-methyl-6-(p-dimethylaminostyryl)-4H-pyran (DCM) laser dye covers most of the rotational Stokes shift even for spectra at 1000 K or higher, and multiple species can be detected within the same spectral range as well. Since both, first pump- and Stokes beam in the respective level scheme (cf. Figure 2) originate from the same Stokes laser, additional spectral noise averaging takes place which makes this technique less susceptible to mode noise in the laser sources. Problems in this technique are stray light from the pump beam as well as a lower-temperature measurement accuracy at high temperatures.

2.2.2 Degenerate Four Wave Mixing

Degenerate four wave mixing (DFWM) has emerged as a spatially resolving diagnostic technique with high sensitivity, which can be applied to all species exhibiting an absorption spectrum. Since the method does not need the species to fluoresce, it constitutes an alternative to LIF. As a special case of more general multicolor resonant four wave mixing techniques, DFWM can be visualized as a laser-induced grating (LIG) process,\textsuperscript{(67,68)} in which two beams of equal intensity at wavelength $\lambda$ are crossed at a half angle $\theta$ in the probe volume. If the wavelength of these “writing” beams is tuned into resonance with a molecular transition, then for parallel linear electric field polarizations, a spatially sinusoidally modulated population grating (PG) with wavelength $\Lambda$ equal to $\Lambda = \lambda/(2 \sin \theta)$ will be formed by absorption in the interference region of both beams. This PG can be “read out” by a third, weak probe beam at the same wavelength under the phase matching angle. From a perturbative treatment of the nonlinear interaction process in a two-level atom with a saturating pump- and weak probe and signal beams by Abrams and Lind,\textsuperscript{(69)} the spectrally integrated DFWM signal intensity (Equation 26) can be written as\textsuperscript{(70)}:

$$I_{DFWM} = \frac{3\pi}{2T_2} (k_1I)^2 \frac{4(I/I_{sat})^2}{[1 + 4(I/I_{sat})^2]^{3/2}} I_{pr}$$

$$k_{12} = \left( \frac{wT_2}{2\hbar c e_0} \right) |\mu_1|^2 N_1$$

In this expression $N_1$ is the population of the lower electronic state, and $|\mu_1|^2$ the dipole transition moment between the excited (index 2) and ground (index 1) energy levels coupled by the laser radiation. $I_{sat}$ is the saturation intensity at line center (Equation 27):

$$I_{sat} = \frac{\hbar c e_0}{2T_1 T_2 |\mu_1|^2}$$

$T_1$ and $T_2$, respectively, denote the population and coherence decay times of the coupled transitions. From

In their pioneering work Regnier and Taran\textsuperscript{(61)} recorded the first CARS spectra of molecular hydrogen in an atmospheric pressure Bunsen flame using a narrowband scanning dye laser as a Stokes beam. Eckbreth\textsuperscript{(62)} introduced single pulse temperature and species measurements by using a broadband Stokes dye laser which covers Raman shifts of the whole investigated spectral branch. Species concentrations can be determined from either the integrated CARS line intensity or its spectral shape\textsuperscript{(63,64)} through calibration measurements and spectral modeling, respectively. For low concentrations the (real) nonresonant contribution $\chi_{nr}$ in the susceptibility, Equation (25), is significant and limits the detection sensitivity due to interference with the resonant contribution. To illustrate this behavior, the real and imaginary susceptibility components determining the CARS lineshape are depicted in the inset of Figure 3 for an assumed low concentration of the resonant species in a nonresonant buffer gas.

Owing to the $\Delta v = 1$, $\Delta J = 0$ selection rules in vibrational Q-branch Raman spectra, individual lines are closely spaced and different laser dyes are needed to cover the whole Stokes wavelengths to detect different species. Alternatively, Aldén et al. excited the pure rotational transitions to enable temperature and species concentration measurements to be
Equation (26) it is obvious that larger signal intensities can be obtained by increasing the intensities of the incoming beams, although saturation effects will make quantitative interpretation of experimental results difficult. In the limit of laser intensities much larger than the saturation intensity of the probed transition, the expression for the DFWM signal intensity (Equation 26) reduces to

\[ I_{\text{DFWM}} = \frac{k_{12}^2}{T_2} \left( \frac{I}{I_{\text{sat}}} \right)^{1/2} I_p \propto \mu_{12}^2 N_1^2 \left( \frac{T_2}{T_1} \right)^{1/2} I^{1/2} \gg I_{\text{sat}} \]

(28)

which shows a reduced sensitivity on the dipole moment \( \mu_{12} \) and relaxation times \( T_i \) of the transition. Since in practical measurements laser intensities often are high enough at least partially to saturate the transitions, the DFWM signal intensity varies with laser intensity in between those given by Equations (26) and (28), and the correct power dependence of the dipole moment has to be determined experimentally. In addition, some theoretical modeling of saturated DFWM has been performed to quantify temperature and concentration measurements for NO and OH in flames at various pressures.

Also, the strong pressure dependence of the DFWM signal intensity in the linear regime can be reduced by working at saturating laser intensities. As has been confirmed by experiment and numerical calculations, a most useful range is \( I_p \approx 2I_{\text{sat}} \). Modeling of the pressure dependence of the DFWM signal at saturating laser intensities, using direct numerical integration (DNI) instead of the stationary absorber model of Abrams et al. gave good agreement with corresponding measurements with NO. The capability of DFWM to probe nonfluorescing species sensitively has been exploited for monitoring highly predissociative states such as CH$_3$. Since the increasing availability of tunable infrared radiation from OPOs the opportunity to monitor hydrocarbons (CH$_4$, C$_2$H$_2$) via DFWM by excitation of their characteristic rovibrational transitions has been exploited. If narrow bandwidth tunable lasers are employed in the phase conjugated beam geometry, where both pump beams are counterpropagating, sub-Doppler DFWM lineshapes can be obtained. This is demonstrated in Figure 4, where individual LIF (solid line without dots) and DFWM rotational lines from the O-branch of the \( \Lambda^2 \Sigma^+ - X^2 \Pi(0, 0) \) transition of NO at 226 nm are compared at low pressure. In contrast to the DFWM spectrum, which shows almost no background interference, the LIF profile is dominated by the room temperature Doppler line profile with superimposed saturation dips at line center, where the frequencies from all beams observed in the molecular frame of reference coincide.

![Figure 4](image.png)

Figure 4 Comparison of LIF (pure solid line) and DFWM (line with dots) lineshapes in the O-branch spectrum of the \( \Lambda^2 \Sigma^+ - X^2 \Pi(0, 0) \) electronic band of NO. Using a narrowband laser system the Doppler broadened LIF and the almost Doppler-free DFWM lineshapes acquired in the phase conjugated beam geometry are clearly distinguished. Total NO pressure in the cell was 2.7 Pa.

At pressures high enough to quench efficiently the excited state population created by the two grating forming beams within the laser pulse duration, the excitation energy is translated into heat, which gives rise to a thermal grating (TG) signal in the medium. The purely TG signal contribution can be probed in the direction of the Bragg angle \( \phi_B \) for the grating wavelength \( \Lambda \), \( \sin \phi_B = \lambda_{pr} / 2 \Lambda \), if the wavelength \( \lambda_{pr} \) of the reading beam is not resonant with any transition in the molecule. These data enable single shot measurements to be made of the sound velocity and thermal diffusivities in a localized volume of the sample at high pressures. Efficient electronic quenching of excitation energy, therefore, is beneficial in LIG spectroscopy compared to LIF. The method also has been applied for the detection of OH in a high-pressure premixed methane/air flame. Through fitting of the experimental LIG temporal signals trace good agreement of the gas temperature with nitrogen CARS thermometry at the same location in the flame has been obtained.

2.2.2 Polarization Spectroscopy

Polarization spectroscopy (PS) is a two-beam technique, in which one pump and one probe beam are crossed in the sample and the depolarization of the probe beam is monitored through crossed polarizers. The first implementation of PS by Teets et al. showed it to be a versatile alternative to high-resolution gas phase saturation spectroscopy. For combustion diagnostics
Nyholm et al.\(^{(83)}\) demonstrated its potential as a spatially resolved and background free absorption technique with good sensitivity for the detection of minor species.

The principles of PS are outlined in early publications\(^{(82,84)}\) and textbooks.\(^{(8)}\) The pump beam creates an anisotropy in the sample by selective absorption within the degenerate magnetic sublevels of the probed transition. This anisotropy causes rotation of the plane of polarization of the probe beam and a depolarization through differential absorption and refraction for the left and right circularly polarized components of the linearly polarized probe light, respectively, which is detected through a crossed polarizer in the probe beam path. For this case the transmitted beam intensity can be described according to Equation (29) as\(^{(82)}\)

\[
I_{PS} = I_0 \frac{x \theta^2 + b^2}{2 + x^2} + \frac{1}{2} \Delta k_{12} l \cdot x \frac{1}{1 + x^2}
\]

\[
+ \left( \frac{1}{4} \Delta k_{12} l \right)^2 \frac{x}{1 + x^2} \tag{29}
\]

which is a combination of Lorentzian and dispersive contributions to the total line profile: the first three terms are frequency independent and are caused by residual transmission of the polarizers (\(\xi\)), their accidental uncrossing (\(\theta\)) and a possible residual dichroism (\(b\)) of the optics between both polarizers in the probe beam path. The differential absorption coefficient for left and right circularly polarized light, \(\Delta k_{12}\), at resonance \(x = w_{l2} - w_I = 0\) is given by Equation (30)

\[
\Delta k_{12}(x = 0) = \Delta k_{12}^0 = k^+ - k^- = k_{12}^0 S_0 C_{rj}\tag{30}
\]

where \(S_0\) is a saturation parameter and \(C_{rj}\) are Clebsch–Gordan coefficients for the respective transition and coupling cases. For sensitive species detection, \(b\) and \(\theta\) should be minimized, which makes this diagnostic difficult when probing, for example, through optical windows. Depending on the relative importance of these terms in \(I_{PS}\), purely dispersive or Lorentzian lineshapes can be obtained. For the special arrangement with perfectly orthogonal beam polarizations (\(\theta = 0\)), and stress free window mounting (\(b = 0\)) the signal intensity at line center (\(\Delta x = 0\)) and for a linearly polarized pump beam is given by Equation (31):

\[
I_{PS} = I_0 e^{-k_{12}l} \xi + \frac{1}{2} \theta^2 k_{12}l + \left( \frac{\Delta k_{12} l}{4} \right)^2 \tag{31}
\]

2.2.4 Sum Frequency Generation

Many combustion processes are influenced and can be guided by heterogeneous chemical reactions. Prominent examples are the exhaust gas treatment in automotive engines for reduced emission of hydrocarbons and NO\(_x\) for better fuel economy and environmental acceptance. To obtain most direct information on the chemistry in heterogeneous catalytic combustion processes, apart from linear absorption/reflection UV/visible and infrared spectroscopy, surface sensitive laser spectroscopic probes are of great value. Sum frequency generation (SFG) provides such possibilities since it is surface and species selective within the whole technically interesting pressure range.\(^{(85)}\)

SFG was first observed in anisotropic crystals, where the proper superposition of two laser beams at frequencies \(w_1\) and \(w_2\) can generate a second order polarization \(P^{(2)}(w_3 = w_1 + w_2)\), which gives rise to the coherent radiation of a third beam at the sum of both frequencies.

Because of symmetry considerations, second order phenomena only arise to a significant extent in non-centrosymmetric media. In reflection from a surface this condition is not satisfied for the bulk material but only for a small surface layer of thickness \(\sim \lambda/2\pi\), where the symmetry is broken. As in any nonlinear spectroscopic technique, the SFG signal intensity can be enhanced several orders of magnitude if the waves interact resonantly with a vibrational mode of \(w_v\) of species which form the molecular surface layer. This property has triggered numerous activities using SFG as a sensitive surface-specific monitor for probing surface coverage, molecular structure and chemical reactions at solid or liquid interfaces. SFG, therefore, is of fundamental interest for the study of heterogeneous combustion and catalysis, sensor development, etc.

The SFG intensity at frequency \(w_{\text{SFG}} = w_{\text{sys}} + w_v\) is proportional to the squared modulus of the second order susceptibility, \(\chi^{(2)}_{\text{SFG}} = \chi^{(2)}_{\text{IR}} + \chi^{(2)}_{\text{Raman}}\), and can be written for a surface adsorbed species with \(n\) active vibrations according to Equation (32) as\(^{(86,87)}\)

\[
I_{\text{SFG}} = K_{\text{sys}} |F(\chi_{\text{IR}}^{(2)} + \chi_{\text{Raman}}^{(2)})|^2 \tag{32}
\]

In this expression, \(K_{\text{sys}}\) is a geometry-dependent factor which also contains a correction for the local field effects in the interaction layer. The nonlinear optical susceptibility, \(\chi^{(2)}_{\text{SFG}}\), is the macroscopic form of the molecular hyperpolarizability \(\beta\). From a quantum mechanical derivation of this expression, Equation (33)

\[
\beta_{\nu,lm}(w_{\text{SFG}}) = \frac{A_{\nu,lm} M_{\nu,n}}{h(w_v - w_{\text{IR}} + i\gamma)} \tag{33}
\]

it can be seen that since both the infrared (\(M_{\nu,n}\)) and Raman (\(A_{\nu,lm}\)) transition moments to appear, the vibrational mode to be excited in the surface bound molecule must be infrared and Raman active.
Figure 5 Experimental arrangement for SFG for the in situ detection of chemisorbed molecules on platinum surfaces. The visible fixed frequency (532 nm) and tunable infrared beam are derived from the second harmonic of a ps-Nd:YAG-laser and a lithium borate (LBO) optical–parametric generator/amplifier (OPG/OPA), respectively. AgGaS2-OPG, silver-gallium-sulfide optical parametric generator; QMS, quadrupole mass spectrometer; AES, Auger-electron spectrometer; LEED, low energy electron diffraction; MC, monochromator; PMT, photomultiplier tube.

Figure 5 depicts an experimental example of the use of a SFG spectrometer to study chemical reactions on surfaces. It consists of a laser system which provides fixed visible (532 nm from a frequency doubled Nd:YAG-laser) and tunable infrared (2–10 µm) wavelengths in short (30 ps) high-intensity pulsed beams that generate the SFG signal in the visible for detection with a filtered photomultiplier. The two beams are sent through CaF2 windows to the specimen surface mounted in a high-vacuum chamber for preparation and analysis. The system is capable of investigating desorption phenomena on surfaces, bridging the pressure gap from ultrahigh vacuum up to 1 atmosphere (1 atmosphere (technical) = 10^5 kPa).

### 2.2.5 Multiphoton Absorption Spectroscopy

Several constraints limit the direct excitation of single photon transitions in atoms or light molecules in flame environments: deep UV radiation can be absorbed nonspecifically by other species in the flame because of the dense electronic bands in this wavelength range. This can cause interfering fluorescence or bias absorption measurements. An additional complication arises from laser-induced chemistry at short wavelengths, that is, the production of reactive atoms through multiphoton absorption (MPA) and subsequent photodissociation or ionization processes during the laser pulse duration.\(^{(88)}\)

The first constraint can be circumvented by MPA spectroscopy, where visible or near UV laser radiation can be used. Owing to the high intensity of focused laser beams this method still shows sufficient sensitivity as a viable combustion diagnostic technique. As an example, the MPA technique enabled detection of CO at 230 nm\(^{(89)}\) via the strong B^1Σ^+ ← X^1Σ^+ two-photon absorption, and of NO\(^{(90)}\) in atmospheric pressure flames. Quenching and possible predissociation of the upper excited state limit detection sensitivity and make calibration procedures necessary.\(^{(91)}\)

The transition probability \(W^{(n)}\) for \(n\)-photon transitions is determined by the MPA cross-section \(\sigma^{(n)}\), the relevant laser intensities \(I_i(w_i)\) and their respective photon energies \(\hbar w_i\) (Equation 34):\(^{(88)}\)

\[
W^{(n)} = \frac{\sigma^{(n)} I_1(w_1) \cdots I_n(w_n)}{\hbar^{n} w_1 \cdots w_n} \tag{34}
\]

Crosley and Smith\(^{(92)}\) determined experimentally an absolute two-photon cross-section of approximately \(10^{-50}\) cm\(^4\) s for excitation in the \(A^2Σ^+ ← X^2Π_j(0, 0)\) electronic system of OH in the burnt gases of a methane air flame. This value already is 3–4 orders of magnitude lower than a corresponding two-photon transition.
of atoms. Therefore, high pulse energies are beneficial in multiphoton spectroscopy as long as disturbing effects originating from power broadening, gas breakdown and ac-Stark effect can be neglected.

2.2.6 Resonance Enhanced Multiphoton Ionization

Absorption of multiple photons can ionize the probed species and the ions/electrons formed in the last step can be detected with very high sensitivity. This can be done either in situ through measurement of the current between two electrodes or through withdrawal of small gas samples from the probe volume with subsequent ionization and detection in a mass spectrometer. If a \((2 + 1)\)-REMPI (resonance enhanced multiphoton ionization) process is considered (two-photon allowed transition to a resonantly excited intermediate state \(k\) at frequency \(w_2\), followed by a one-photon ionization step, see Figure 2), a simplified expression for the ionization current as a measure of species density results in (Equation 35)\(^6\)

\[
S_{\text{REMPI}} = N_1 \frac{\sigma_{1k} \lambda_{1,1}^2}{1 + (A_k/\sigma_{kl} \lambda_{1,2})} \quad (35)
\]

In this expression, \(N_1\) is the population of the ground electronic state, \(\sigma_{1k}\) the absorption cross-section (per molecule) for the two-photon transition involved, \(n_{1,1}\) the number of incident laser photons at frequency \(w_1\), \(\sigma_{kl}\) the ionization cross-section from intermediate level \(k\), and \(n_{1,2}\) the number of photons in the ionizing laser pulse.

3 APPLICATION OF LASER-BASED TECHNIQUES

3.1 Detection Sensitivities

Detection sensitivities attainable in combustion environments are essential parameters for the application of the various laser-based techniques described in the previous paragraphs. These limits cannot be stated generally since they depend on the line strength of the species to be detected, system parameters like absorption length, response time or optical output power,\(^9\) while especially for in situ measurements temperature and pressure in the probe region and disturbing effects of the in situ beam path (dust, background emission) are most important factors for system specific detection limits. A figure of merit for absorption spectrometers is the minimum detectable absorption change (MDA = \(\Delta I/I_0\)). In a precisely controlled absorption cell an MDA of \(10^{-3}\) is achievable with noncoherent light sources on a routine basis, while the best laser-based spectrometers provide MDAs in the \(10^{-6}\) range, resulting in a dynamic range of \(10^2\) to \(10^7\). Table 1 is a far from complete collection of experimental work in the literature with stated detection limits of combustion of relevant minor species for the various techniques introduced here under different pressures and environments to give a general impression of their practical applicability.

Species selectivity is another feature which has improved greatly through the introduction of lasers, since high radiance and small source linewidth are available simultaneously. For the case of continuous wave-lasers (diode- and dye-lasers) the laser linewidth can be of the order of 10 MHz, compared to molecular linewidths in the gas phase of several 100 MHz under low pressure conditions and several gigahertz at atmospheric pressure. Ultimate selectivity can be ensured, if a spectral region, a so-called “spectral window”, can be found where the species under investigation is the only (or at least the dominant) absorber.

3.2 Laminar Flames

3.2.1 Low-pressure Flames

Laminar premixed flames at low pressure on a flat flame burner constitute an ideal experimental arrangement for studying the interaction of elementary chemical combustion mechanisms. Experimental data on temperature as well as on concentration profiles for stable and unstable species are used to validate and develop further mathematical models which predict these profiles by numerical solution of the underlying conservation equations, including convection and molecular transport processes.

Figure 6(a) shows such an arrangement used for a low pressure \(\text{CH}_4/\text{O}_2/\text{NO}\) flame. Absolute concentration profiles of methyl and hydroxy radicals as well as nitric oxide are measured by LAS. CH and CN radicals are followed by LIF. As shown in Figure 6(b) the shape and absolute values of the concentration profiles for OH and \(\text{CH}_3\) radicals as well as the initial reduction of nitric oxide are predicted well by the models. However, absolute CN radical concentrations\(^{111}\) are significantly overestimated by all models (lines). More work has to be done on the details of the formation and destruction of CN during the reduction of nitric oxide in the reburn process. Further improvement in sensitive absorption spectroscopy in flames can be obtained by using longpath absorption techniques such as CRLAS\(^{19}\) and intracavity absorption (cf. section 2.1.1).

REMPI, combined with molecular beam sampling mass spectrometry, is a highly selective and sensitive technique for combustion diagnostics and environmental chemical analysis.\(^{185}\) Detection sensitivities in the lower parts per billion to parts per trillion (per volume) range of chloroethylenes, toluene and \(p\)-chlorophenol have been obtained in helium carrier gas, whereas
Table 1 Detection limits for minor combustion-relevant species of various linear and nonlinear laser spectroscopic techniques. The spectroscopic transitions probed for each species, their transition frequency (in cm\(^{-1}\)), total pressure \(p\), an estimate of the temperature \(T\), and the sample environment are given. The detection limits are approximate values, either determined directly or extrapolated from the respective experimental data.

\(^b\) \(1(11) = 1 \times 10^{11}\).

\(^c\) Mostly estimated temperatures.

\(^d\) 1,1-Dichloroethene.
because of cross-sensitivities and nonresonant multiple species ionization, this limit increases into the percent range in sample mixtures directly withdrawn from real world industrial devices. To increase selectivity, with

an appropriate choice of excitation wavelengths various electronic transitions in large molecules can be accessed in one- or multiphoton transitions from which ionization is accomplished in a second step at the same or a
separate laser frequency. Portable instruments have been designed which offer sufficient flexibility in switching between different laser wavelengths for the excitation of numerous unsaturated hydrocarbons, radicals and polycyclic aromatic hydrocarbons (PAHs) for monitoring in real time. An example is the extraction and sensitive on-line REMPI detection of automotive exhaust gas pollutants at different engine loads and speeds.\(^6\)

Laser ionization mass spectrometric detection also has been employed successfully for spatially resolved species analysis in low-pressure sooting flames to enlighten the chemical kinetic mechanisms responsible for soot precursors and particle growth. Most soot precursors possess absorption maxima between 200–300 nm with ionization thresholds between 6 and 9.5 eV. Special scavenging techniques allow the sampling and subsequent REMPI/mass spectrometric analysis of possible radical precursors as important building blocks for the growth history of soot particles and carbon cages such as C\(_{60}\), C\(_{70}\) in flame gases. Homann et al.\(^{112}\) determined correlations between the number of hydrogen and carbon atoms contained in highly condensed isomers of PAHs as precursors of C\(_{60}\), and observed their formation and destruction in low-pressure sooting flames. These authors claim the C\(_{60}\) cage is the final product in the chain of hydrogen abstraction, folding, condensation and isomerization of smaller fragments of five- and six-membered aromatic ring condensates.\(^{112,113}\) The detailed study of the fragmentation behavior, ionization efficiencies and absolute calibration of a variety of PAHs is essential for quantitative comparisons with numerical modeling of soot in flames.\(^{114}\)

3.2.2 Higher Pressure Flames

In laminar flames spatially resolved temperature measurements using CARS are possible with high precision. Figure 7 shows a comparison of the temperature readings deduced from the pure rotational spontaneous Raman spectrum (squares) and the Q-branch vibrational CARS spectrum of molecular nitrogen (triangles) acquired at the same location and under the same operating conditions in a stable high-pressure premixed methane/air flame. Both data sets agree within the 3% limit of precision estimated from the spontaneous Raman data.\(^{115}\) The pure rotational spontaneous Raman spectra exhibit well-resolved lines even at the highest pressures investigated. The spectrally dense CARS Q-branch of N\(_2\) suffers partial collisional collapse of its rotational structure at the band origin which usually degrades the temperature measurement accuracy at low temperatures (300–700 K) and higher pressures.\(^{116}\) Temperature measurements using pure rotational CARS have also been done in laminar flames and often are an alternative if higher precision is required in the low temperature (300–870 K) higher pressure (1–15 bar) regime.\(^{117}\)

To detect minor species, fully resonant nonlinear techniques, such as DFWM, PS and resonance enhanced CARS are necessary to achieve sufficient detection sensitivity. DFWM spectra of electronic transitions have been recorded and gas temperatures have been determined in flames from OH, NH,\(^{103}\) NO,\(^{75,118}\) CN,\(^{119}\) CH,\(^{120}\) and in cell experiments from NO\(_2\),\(^{120}\) and HCO.\(^{121}\) Using PS important radicals in flames such as OH and NO were analyzed by Nyholm et al.\(^{83}\) and Löfstedt et al.\(^{122}\) respectively. The potentials of PS for two-dimensional imaging of these species and for single shot temperature measurements were also shown.\(^{122,124}\) Because the total angular momentum of the photon-molecule system is conserved during the interaction process, a proper choice of beam polarizations can be exploited to excite selectively P-, Q- or R-branch transitions. Careful modeling of the PS spectral structure for OH and NH is essential for in situ temperature measurements in atmospheric pressure flames.\(^{125}\) Recently, the intensity and collision frequency dependence of PS signal intensities has been modeled using the rigorous approach of DNI of the Liouville equation for the density operator,\(^{126}\) which promises to address more closely these effects in practical measurement situations. To increase the Raman-resonant susceptibility in a CARS interaction process, Stokes-, pump- and the generated anti-Stokes-signal frequency should be tuned close to one-photon allowed electronic transitions in the molecule studied. This makes the experimental approach rather complicated, since up to three narrowband tunable laser systems

---

**Figure 7** Comparison of measured temperatures (deduced from fitting spectral shapes) in a methane/air flame at various pressures. Spectra were obtained either from spontaneous pure rotational Raman scattering (squares) or from Q-branch vibrational CARS (triangles) measurements of molecular nitrogen at the same location in the post flame gases.\(^{115}\) Dashed lines are the ±3% temperature measurement accuracies inherent in fitting results from the spontaneous Raman data.
have to be employed. Nevertheless, spatially resolved measurements of \( C_2 \) and \( \text{OH} \) distributions in various pressure flames have been performed by Attal et al., proving high detection sensitivities.\(^{(94,97)}\)

### 3.3 Turbulent Combustion

Fundamental studies of flames are based on different experimental set-ups tailored to select certain aspects of combustion. Technical processes usually rely on non-premixed, turbulent combustion for reasons of efficiency and safety. This information about chemistry–turbulence interaction and complex recirculating flows is necessary to invent models suitable for simulating technically relevant flames. The understanding of the underlying processes is best verified through a direct comparison of numerical model results with experimental measurements of properties such as temperature and species concentrations. Furthermore, detailed knowledge of the underlying flow field patterns is essential.

Laser-based techniques are ideal for studying turbulent processes since they do not disturb the flow and, using pulsed lasers, they are fast enough to resolve the smallest relevant timescales. Statistical investigations of correlations of temperature and concentration of different reactive species were investigated by using point measurements based on Rayleigh and Raman scattering and LIF diagnostics. Quantitative comparisons of the thermochemical states in turbulent flames with idealized representations, such as steady strained laminar flames, perfectly stirred reactors, or adiabatic equilibrium are thus possible. Comparisons with DNS calculations on the other hand give insight into the validity of some of the basic assumptions that turbulent combustion models are built upon and allow for the evaluation of the predictive accuracy, strengths and limitations of a wide variety of combustion models.

There has been increasing interest in revealing the structure of turbulent flames and this was addressed using laser imaging for temperature, mixture fraction and reactive species such as \( \text{OH} \) and \( \text{CH}_4 \).\(^{(127)}\) Simultaneous measurements of these quantities yielding scalar dissipation rates are critical for the validation of turbulent combustion models describing molecular mixing and extinction processes. Simultaneous measurements of RS and fuel Raman imaging provide information about temperature distribution and mixing. Both can be used to quantify further OH-LIF data by correcting for temperature and collisional quenching effects. These measurements (cf. Figure 8) showed the correlation of reaction zone width and jet Reynolds numbers and addressed the influence of local dissipation rate on flame extinction.\(^{(128)}\) A review article that covers this topic in detail is given by Masri et al.\(^{(129)}\)

![Figure 8](image-url)

**Figure 8** Images of mixture fractions (\( \xi \)), scalar dissipation rates (\( \chi \)), temperatures (\( T \)) and \( \text{OH} \) concentrations in turbulent \( \text{CH}_4/\text{air} \) diffusion flames obtained by two-dimensional-Raman, Rayleigh- and LIF-spectroscopy.\(^{(128)}\)

With careful spectral filtering Raman measurements are possible even in dense media involving strong Mie scattering from small droplets. By forming a thin light sheet from the output beam of a XeF-excimer laser at 351 nm, Decker et al.\(^{(130)}\) were able to image the Raman scattered light from a dense cryogenic jet of liquid nitrogen onto a CCD camera to study the evaporation and breakup of the fluid nitrogen exiting through a small (1.9-mm diameter) nozzle as employed in rocket engines, and performed temperature and density measurements (from the Stokes/anti-Stokes intensity ratio and the Rayleigh intensity, respectively).

There are numerous applications of CARS as a temperature measurement technique in turbulent combustion processes. From the Q-branch spectrum of nitrogen temperature measurement accuracies of 2\% or better within a single laser pulse have been obtained.\(^{(131)}\) and applications have spread into diverse fields of technical combustion systems such as liquid fuel combustors and swirl burners,\(^{(62)}\) engine combustion,\(^{(132)}\) gas turbines and jet propulsion devices.\(^{(133–135)}\) High-resolution lineshape measurements of combustion relevant species, such as \( \text{N}_2, \text{O}_2, \text{H}_2, \text{CO}, \text{CO}_2 \) and \( \text{NO} \)\(^{(141)}\) have improved modeling of CARS spectra, an important prerequisite for precise temperature measurements through spectral simulation. Figure 9 shows temperature profiles from single shot broadband nitrogen CARS thermometry across the shear layer region of a supersonic air-fed combustor fueled with hydrogen.\(^{(134)}\) The symbols connected
Figure 9 Temperature distribution deduced from H$_2$ Q-branch CARS spectra across the shear layer of a supersonic hydrogen fueled combuster. The inserts at three measurement locations also depict single shot histograms with relative standard deviations (S.D.) of temperature at different heights (HT) from the wall.

by straight lines depict the mean temperature across the shear layer which is formed after injection of the fuel hydrogen into the supersonic air flow; it slowly decreases as the measurement point moves upstream. The necessity to do single pulse measurements is clearly demonstrated, however, in the temperature histograms (inserts, at three measurement locations), illustrating the fluctuation in this parameter as a function of position in the flow. This gives a more detailed picture on the mixing properties and burning behavior of the combuster.

3.4 Engine Combustion

Reducing the release of pollutants is of particular interest in improving the environmental acceptance of combustion processes. The following discussion focuses on NO which is with soot and unburned hydrocarbons one of the major combustion-related pollutants. NO concentration measurements in spark ignition (SI) and diesel engines exciting NO with tunable ArF excimer lasers at 193 nm (σ-bands)$^{142}$ and 225 nm (γ-bands)$^{36}$ are reported. However, to circumvent the strong attenuation of these short wavelengths in many technical combustion systems, excitation of NO with tunable KrF excimer lasers at 248 nm was suggested.$^{144}$ Since then, this technique is frequently applied for quantitative measurements of NO in IC engines.$^{145}$ The excitation laser is tuned to the O$_{12}$ bandhead of the A–X(0,2) transition where the fluorescence excitation
spectrum of molecular oxygen has a local minimum. NO fluorescence emitted in the $A-X(0,1)$ and $A-X(0,0)$ bands at shorter wavelengths is detected which further minimizes the influence of interfering species. Quantification of LIF signal intensities requires detailed knowledge of several temperature and pressure-dependent factors. Variation of absorption spectra due to line broadening and shifting\(^{146}\) change the spectral overlap of laser profile and absorption line.\(^{29}\) Collisional quenching leads to a decrease of the fluorescence lifetime by radiationless deactivation of excited molecules and therefore, has to be included in the data reduction.\(^{147}\) The simultaneous application\(^{145}\) of RS and LIF for measurements of temperatures and NO concentrations in an IC engine is shown in Figure 10. From the image pairs with corresponding NO concentrations and temperature fields it can be seen that NO is formed in areas of high temperature. While the overall spatial distribution of NO and temperature is strongly correlated, the profiles in Figure 10 indicate that the temperature distribution is more uniform than the NO concentration distribution. This is an important result for comparison with mathematical models which are developed for engine design. Owing to the strong nonlinear temperature dependence of the NO production rate, careful control and homogenization of the combustion conditions should allow significant reduction of primary NO formation.

Valuable information for most major species in engines can again be obtained from SRS. Grünefeld et al.\(^{148}\) performed spontaneous Raman imaging along a line with noise levels of a few per cent in a single shot using the beam of a KrF excimer laser at 248 nm with spectral as well as spatial dispersion of the scattered light accomplished by mounting an intensified CCD camera in the exit plane of a spectrograph. The larger scattering cross-sections in the UV allows imaging of the scattered light with smaller collection optics and therefore measurements in technically relevant devices such as engines and boilers. By taking advantage of the highly polarized Raman and Rayleigh scattered light in comparison with unwanted laser excited fluorescence and stray light from enclosure walls, they were able to monitor major species in an isooctane spray flame burner and a four cylinder in-line engine by subtracting spectra taken with mutually perpendicular polarization of the exciting laser beam.

The most accurate spatially resolved temperature measurements in engines can be performed with CARS as long as beam steering effects which severely degrade the CARS signal generation process can be tolerated. Therefore, precise cycle-resolved thermometry is possible in the compression stroke prior to ignition\(^{149}\) and in the expansion stroke when the flame front has traversed through the focal volume of the beams.\(^{150}\)

![Figure 10](image-url)

Figure 10 Simultaneous single-shot absolute NO concentration (left image) and temperature (right image) fields in a transparent SI-engine fueled with propane/air ($\lambda = 1$) using two-dimensional-LIF and RS.\(^{145}\) In the lower graph are depicted plots of the respective data points (NO: filled circles, Temperature: open circles) along the straight lines given in the respective images.

In any case the USED (unstable resonator enhanced detection) CARS phase matching beam geometry\(^{133}\) is preferred in such measurements to minimize beam steering effects.

### 3.5 Coal and Waste Combustion

For large scale combustion systems such as power plants, incinerators and heavy industries, tight monitoring and control of combustion is of great importance for a clean environment. However, these applications need ruggedized, compact and reliable laser spectroscopic instruments. Species concentrations,\(^{11,151}\) temperature\(^{152}\) and other physical parameters like mass flux and pressure\(^{11}\) can be directly inferred from absorption lines of the major species such as $H_2O$, $O_2$, $CO_2$, or $CH_4$ within the combustion chamber or exhaust channel by inexpensive and compact room temperature near-infrared diode lasers (NIRDL) via overtone and combination bands in the near-infrared (0.75–2 µm) spectral region. Water present in high concentrations in all hydrocarbon bands in the near-infrared (0.75–2 µm) spectral region. Water present in high concentrations in all hydrocarbon
the temperature from the ratio of the peak absorption coefficients. An improved version of this device extracted characteristic fast temperature variations within the flue gas duct (diameter 18 cm) of a pulsed 50-kW incinerator and used the root mean square average ($T_{RMS}$) of the 183-Hz frequency component to establish an active closed-loop control of the CO emission by optimizing the relative phase angle $\phi$ between the primary and secondary air injection valves which are pulsed at identical frequency $f_0$ (Figure 11). Another successful NIRDL-based sensor development for active control purposes is the simultaneous in situ detection of $\text{O}_2$ and $\text{H}_2\text{O}$ in the combustion chamber (diameter 4 m) of a 20-MW-waste incinerator, which aims to optimize the secondary air injection. This sensor provides an important contribution to the complex combustion control system (CCS) depicted in Figure 12. It was used to ensure a highly efficient and environmentally safe waste incineration by actively optimizing the selective non-catalytic reduction (SNCR) with a $\text{CO}_2$-LISA. In addition, the primary air injection, grate movement and fuel input are under closed-loop control through an infrared scanner camera (TACCOS) measuring the waste bed temperature.

Numerous disturbances caused by the in situ path such as transmission fluctuations and thermal background emission, which interfere with the molecular absorption signal had to be suppressed completely. The laser signals were verified by extractive reference sensors, which probe the cold flue gas duct and provided a linear response with a sensitivity of about 0.3 volume% and a temporal resolution of 1 s. Since gas transport to the sensor could be avoided, the laser signals are up to 60 s faster than the reference signals. The recent version of this sensor was improved further by fiber coupling the laser and by an inexpensive, compact and robust analog data evaluation so that the NIRDL-based in situ species sensors are attractive tools for industrial control purposes.

Excimer laser-induced fragmentation fluorescence (ELIF) is another laser spectroscopic sensing technique, which proved its suitability for industrial combustion control applications, by in situ detection of alkali compounds. These substances which are present in the flue gas of various combustion processes can cause severe corrosion damage to the high-temperature gas turbines needed for high efficiency pressurized
coal combustion.\textsuperscript{(159,160)} In ELIF an excimer laser photodissociates gaseous alkali compounds within the flue gas duct and generates electronically excited alkali atoms (Na(3\textsuperscript{2}P), K(4\textsuperscript{2}P)), which are then readily detected by their fluorescence in the visible region via a fiber-coupled two species detection system as depicted in Figure 13. The measured signals are converted to absolute concentrations by calibration of the complete detection apparatus under known thermodynamic conditions. A detection limit of 0.2 ppb could be established for both alkalis at 10 bar total pressure and 800°C gas temperature. An expansion of the principle to the detection of heavy metals is in preparation, so that this sensor promises to become an important tool to control the efficiency of alkali flue gas filters and to optimize the combustion process in order to minimize the release of alkali and heavy metal compounds.

Figure 12 Intersection through the waste incinerator at which the in situ detection of O\textsubscript{2} and H\textsubscript{2}O has been performed. A selection of important sensors (diode laser in situ sensor, laser in situ ammonia monitor, laser based in situ ammonia monitor (LISA), and infrared scanner camera, thermography-assisted combustion control system (TACCOS)) as well as the possible actors which are connected to the CCS, are indicated.\textsuperscript{(156)}

4 FUTURE DEVELOPMENTS

After about two decades of research and development in the area of laser-based concepts for combustion diagnostics many of the spectroscopic methods have matured from qualitative to quantitative techniques. A closer and more direct relation to engineering and development purposes is the application of laser-imaging diagnostics to IC engines. Once optical access has been achieved for a given device, temperature, gas and particle velocities as well as a variety of species can be studied. By identifying problems with fuel intake and mixing in engines via gaseous fuel imaging and detection of fuel droplets by Mie scattering together with the corresponding temperature information, one can optimize the cold start behavior of Otto engines and control soot formation in direct-injection diesel engines.
The cold start accounts for a major part in unburnt hydrocarbon emission from automobiles. A detailed knowledge of the fuel evaporation process is also of basic importance for gas turbines in power plants and jet engines. In all these areas, laser-based techniques are now on the way to move from the research laboratories into the development departments.

Another area of high technological relevance is the interaction of turbulent reactive flows with the walls of the technical installations. Heterogeneous processes at the surface as well as mass and energy transfer to the turbulent boundary layer are important parameters of the optimization, not only of combustion processes, but also for industrial chemical reactors. Using imaging experiments together with detailed numerical simulations one can elucidate microscopic details in terms of underlying elementary processes and optimize industrial installations.

The application of modern high power UV-laser systems as well as robust and low cost semiconductor-based detectors and laser diodes offers many new possibilities for intelligent CCSs in new power plants with combined cycle operation as well as in the efficient use of refuse for the production of thermal and electrical energy. The large amount of information provided by these new laser-based detection schemes can be used in modern fuzzy logic and neural network-based control systems.

Laser multidimensional imaging of the interaction of turbulent flow fields with combustion can be done by diode pumped high repetition rate solid state lasers which finally will provide a full time development visualization. Short pulse lasers with picosecond and femtosecond pulse length can be used to investigate directly collision and transfer rates which are necessary for quantification of LIF experiments in technical combustion systems.

Laser-induced breakdown spectroscopy (LIBS) is a laser-based technique that can provide nonintrusive, qualitative and quantitative measurement of metals in various test environments. LIBS is an emission-type technology that has been successfully applied to gas, liquid, and solid samples. The major advantages of LIBS compared to other analytical techniques is that no time-consuming sample preparation is necessary. LIBS uses the plasma generated by a high-energy laser beam to prepare and excite the sample in one step. It has the ability to perform multielement real-time analysis. Its major disadvantage is that the excitation condition is sensitive to the fluctuation of environmental conditions as well as the laser energy, which can result in poor measurement precision. The small amount of sample material used in LIBS analysis also gives poorer sensitivity for some metals compared to inductively coupled plasma atomic emission spectrometry (ICPAES) and atomic absorption spectrometry (AAS).

The potential of LIBS to detect toxic metals in harsh environments was recognized in the early 1970s. Recent developments towards improving its analytical capability has led to more applications. This article reviews the analytical applications of LIBS with an emphasis on environmental monitoring. A brief review of some fundamental LIBS studies is also given. The analytical abilities of LIBS are compared with some spectroscopic techniques commonly used in the laboratory, such as AAS, ICPAES, and X-ray fluorescence spectroscopy (XFS).

1 INTRODUCTION

Laser-induced breakdown phenomena were observed just after the invention of the laser in 1963. Initial work was focused on understanding the various mechanisms involved in the process. As the material is atomized and excited at the high temperature of laser spark plasma, the potential for using LIBS for elemental analysis was soon recognized by many researchers. The application of LIBS to gases, liquid, and solid samples was explored by various groups from 1970 to 1985. Compared to other analytical techniques, LIBS uses very small amounts of samples, and no sample preparation is necessary. It has the ability to perform real-time analysis because it prepares and excites the sample in one step. The disadvantage of LIBS is that the plasma condition varies with the environmental condition as well as laser energy fluctuation, resulting in poor measurement precision. The microgram-sized samples used in LIBS also causes lower sensitivity for some elements. Since the late 1980s, many studies on LIBS characteristics for quantitative measurements have been initiated. Techniques to improve the precision and sensitivity of LIBS are also being tested. This ongoing development has improved the analytical capabilities of LIBS and led to more applications.

The application of LIBS to environmental monitoring has drawn significant attention. LIBS has been used to detect toxic metals in soil and paint, and has been explored as a multimetal continuous emission monitor (CEM). There are a few reports on the application of LIBS to detect radioactive species. LIBS has also been used to measure the composition of molten metals and glasses. This article reviews the application of LIBS to analytical problems with an emphasis on environmental applications. Detailed reviews on the LIBS principle and other
applications can be found. Brief reviews of some fundamental and experimental application of LIBS are given in sections 2 and 3 of this article. Environmental monitoring applications are discussed in section 4. LIBS’s quantitative capability is addressed in section 5. A brief discussion of future developments is given in the last section.

2 FUNDAMENTAL STUDIES

The physics of laser-induced breakdown has been studied extensively. The minimum optical power density required to form a plasma is called the breakdown threshold; different types of laser, sample, and ambient conditions will have different breakdown thresholds. A laser power density greater than 10^{10} W/cm² is generally required to generate a breakdown in air using a Q-switched Nd: YAG laser of 10–15 ns duration. Breakdown thresholds of solids and liquids are usually much lower than for gases. Table 1 lists some measured breakdown thresholds in different media.

The two mechanisms responsible for electron generation and for growth in laser-induced breakdown are multiphoton absorption and collision-induced ionization. Multiphoton absorption involves simultaneous absorption of a certain number of photons by an atom or molecule, to cause its ionization. This mechanism produces the initial few free electrons in the focal volume. The electron density grows linearly with time. Generally, this mechanism is not the major process in the growth of breakdown thresholds in different media.

where \( N_e \) is the laser pulse width.

The electron density grows linearly with time. Generally, the major process in the growth of the electron density to grow exponentially with time. This process is dominant at high pressure (\( P > 100 \text{ torr in N}_2 \)) and long wavelength (\( \lambda > 1 \mu m \)). The breakdown threshold in this process has a \( \lambda^{−3} \) or \( \lambda^{−2} \) dependence.

The characterization of laser-induced plasma (LIP) has been carried out both in time and spatial evolution of the plasma. The evolution of laser plasma can be divided into several transient phases. The initial plasma (0–100 ns) is characterized by high electron and ion densities (10^{17}–10^{20} cm⁻³), and temperatures around 20000 K. The emission spectrum from the early stage of the plasma is characterized by a continuum background emission due to bremsstrahlung (strong collisions between the free electrons and the excited atoms and ions) and recombination of electrons with ions processes in the plasma. Emission lines from ions and atoms can be found after about 300 ns delay. These lines are superimposed on the strong continuum background. Owing to the high electron density, the emission lines are broadened by the Stark effect. As the plasma expands and cools, the electrons and ions recombine, and a characteristic loud sound can be heard due to the shock wave emitted from the plasma. The continuum background decays rapidly and the atomic emission lines become narrower and weaker. After the initial plasma (>10 μs), the atomic emission decays slowly, and emission from the simple molecule appears. Figure 1 shows LIBS spectra recorded at delay times of 0.25, 5, and 35 μs. As shown in the figure, a properly selected detection window can improve the signal-to-background ratio (\( S/B \)) of the data, which is very important to quantitative measurement.

The excitation characteristics of the laser plasma are determined by the plasma properties, which can be described by the temperature and electron density of the plasma. The analytical measurements are generally performed after the initial plasma, when a state of local thermal equilibrium (LTE) is achieved. At the LTE condition, the analyte intensity is proportional to the relative population of the level, and follows the Boltzmann distribution. The Griem criterion (Equation 1) is usually used to check the existence of LTE in a laser plasma:

\[
N_e (\text{cm}^{-3}) \gg 30 \times 10^{17} \times T_e (\text{K})^{1/2} \times \left( \frac{Z^2}{\lambda (\text{nm})} \right)^3
\]

where \( N_e \), \( Z \), and \( \lambda \) are the critical electron density for LTE, the degree of ionization, and the transition wavelength, respectively.
LASER-INDUCED BREAKDOWN SPECTROSCOPY, ELEMENTAL ANALYSIS

Under LTE, the intensity of an emission line at $v_i$ can be expressed (Equation 2) as

$$I_i = n(hv_i) \frac{A_{ji} g_i}{Q(T)} \frac{e^{-hcE_i/kT}}{h}$$

Here, $n$ is the total number density of a neutral or ion of the element, $g_i$ is the statistical weight of the excited state, $A_{ji}$ is the transition probability, $E_i$ is the energy of the excited state in units of cm$^{-1}$, $h$ is Planck’s constant, $k$ is the Boltzmann constant, $T$ is the plasma temperature, and $Q(T)$ is the partition function.

The details of LIP are described elsewhere. Here, only the characteristic and physics parameters are discussed, which are important to quantitative analysis of LIBS. At present, the physics of LIP is not fully understood but work in this area continues.

2.1 Effect of Physical Variables

Variables that can influence LIBS measurements are laser properties (i.e. wavelength, energy, pulse duration and shot-to-shot power fluctuation), focusing spot size, ambient conditions, physical properties of the sample, and the detection window (delay time, gate width). How these parameters affect the precision and accuracy of LIBS are addressed below.

2.1.1 Laser Parameters

In LIBS, a high-energy laser beam is used to form a plasma to prepare and excite the sample. As the laser plasma is the excitation source of the LIBS measurement, the properties of the laser can influence the analytical qualities of the LIBS measurement. Regardless of the type of laser used, a power density of the order of $10^9$ W cm$^{-2}$ is required. If the laser energy is very close to the breakdown threshold, the pulse-to-pulse fluctuation can cause the plasma condition to be unreproducible, which results in poor measurement precision. The LIBS signal is proportional to the laser energy while the laser plasma is in the optical thin region. Figure 2 shows the dependence of the analyte line intensity and background on laser energy. When the laser energy further increases, it produces a very dense and hot plasma that can absorb laser energy and cause self-absorption. This will lead to an increase in the continuum emission and a decrease in the signal intensity. Laser wavelength can also affect the plasma-formation process. Collision-induced ionization is the dominant process for LIP with a long-wavelength laser. As the laser wavelength decreases, the collision-induced ionization rate decreases, and the multiphoton process increases. A maximum breakdown threshold is found in the intermediate laser wavelength. Laser wavelength can also affect energy coupling between the laser and the sample. Studies have shown that the use of an ultraviolet (UV) wavelength can improve the energy
coupling efficiency due to its low reflectivity for most metals.\(^{14}\)

Studies of laser wavelength on material removal from the sample surface have been performed by many researchers.\(^{15,16}\) Dahmain\(^{17}\) has also derived the mass-ablation rate with absorbed laser intensity \(I_a\), laser wavelength \(\lambda\), and atomic number \(Z\) based on experimental data for a laser energy lower than \(10^{13}\) W cm\(^{-2}\) and \(Z \leq 13\) (Equation 3):

\[
m(kg\ s^{-1}\ cm^{-2}) = 65 \left( \frac{I_a W\ cm^{-2}}{10^{13}} \right)^{5/9} \lambda^{-4/9} \mu m^{-1/4} Z^{1/4} \tag{3}
\]

Besides laser wavelength and laser energy, the laser pulse duration and laser shot-to-shot fluctuation can also affect the signal reproducibility and, hence, LIBS precision. When the laser duration is short compared to electron energy loss time, multiphoton absorption dominates over collision-induced ionization. A study has shown that the threshold intensity increases with decreasing laser pulse duration for laser pulses shorter than \(10^{-7}\) s at atmospheric pressure.\(^{18}\) A 1000-fold higher breakdown threshold was found with an Nd: glass laser of about 10 ps than for a nanosecond width pulse in atmospheric air.\(^{19}\)

2.1.2 Physical Properties of the Sample

All types of material can be sampled using LIBS. However, the physical properties (such as reflectivity of the sample surface, density, specific heat, and boiling point of the target) can have a considerable influence on the result. The surface reflectivity determines the fraction of the laser energy that can be absorbed by a sample, and hence that can affect the material ablation rate. Study has shown that if the laser energy is high enough, the laser energy can still effectively couple to a sample with high reflectivity. This is because, during a laser pulse, the laser energy causes rapid heating of the sample and this results in a sample phase change which significantly reduces the reflectivity.

The laser plasma heats the sample to cause the vaporization and atomization of the sample material. The amount of material vaporized depends on thermal properties of the sample (i.e. conductivity, specific heat, and boiling point). At a low laser power densities, thermal conductivity is the most important parameter for material vaporization. If the material has a high thermal conductivity, the absorbed heat is conducted away quickly and results in a lower amount of material being vaporized. At higher laser power densities, the heat provided is too quickly to be conducted away; therefore, the latent heat of vaporization of the sample becomes a more important factor in determining the amount of material vaporized during a laser pulse.

2.1.3 Focal Properties

High laser power densities can produce a LIP which has higher excitation temperatures with minimum matrix interferences due to more complete atomization. It is a condition preferable to quantitative measurement. The laser power density at the focal volume is inversely proportional to the focused spot size. For a laser beam with a Gaussian profile, the focused beam waist \(w_0\) is given by Equation (4)

\[
w_0 = \frac{\lambda f}{\pi D}
\]

where \(D\) is the radius of the unfocused beam, \(f\) is the focal length of the lens, and \(\lambda\) is the laser wavelength. A higher laser power density at the focal point can be achieved by reducing the focused beam waist using a shorter focal length lens or larger unfocused beam.

Effects of the laser-spot diameter on the sample ablation rates were studied by Wolff-Rottke et al.\(^{20}\) They found the ablation rate increased with decreasing
spot diameter in the range 10–200 μm for a pulse laser. However, if the size of the spark is very small and the distribution of material within it is inhomogeneous, the precision and accuracy of the measurement is degraded.

A short focal length lens is preferred to produce a highly localized spark for a spatially resolved measurement. A long focal length lens provides a larger focal volume and is usually used when the focal lens cannot be kept close to the sample. This situation requires higher laser energy to produce the laser spark, and the larger focal volume associated with the long focal length can cause particle-induced sparks – formed at different locations along the focal axis – and this introduces noise into measurements.

The lens-to-surface distance (LTSD) is a critical parameter for the LIBS measurement of a solid sample. If the laser beam is tightly focused on the surface, a change of the LTSD of a few millimeters can affect the absolute analyte intensity. Studies have shown that by defocusing the laser beam on the sample surface a more reproducible LIBS signal can be obtained. Therefore, this technique can be used to improve LIBS precision.

### 2.1.4 Detection Time Window

In LIBS, the desired atomic emission signal is always accompanied by a strong continuum background. As the continuum background and analyte signal decay with different rates, it is possible to use a time-resolved technique to discriminate against the strong continuum radiation and also avoid spectral interference between species that emit at different times during the plasma decay (see Figure 1). The detection window is selected to obtain an optimum \(S/B\). As the background signal decays at a faster rate than the emission signal, the best \(S/B\) can be achieved at a long delay time. The long delay time also ensures that LTE is achieved. Generally, signal-to-noise ratio \((S/N)\) and \(S/B\) values follow the same trend as the delay time changes. However, a low \(S/B\) can sometimes give a good \(S/N\). Therefore, the selection of the best detection window should depend on both \(S/B\) and \(S/N\).

### 2.1.5 Ambient Conditions

The hot plasma interacts with the surrounding gas by expanding the high-pressure vapor, driving a shock wave into the atmosphere and transferring the energy to the atmosphere via heat transfer and heating by the shock wave. The size and shape of the LIP are largely dependent on the ambient conditions such as pressure, gas composition, mass density of the gas, etc. The breakdown threshold of gas near atmospheric pressure \((10^2–10^3\) torr) has been examined. A pressure dependence of \(P^{-m}\), where \(m\) is close to 1, was found for pulse widths of 10–100 ns. This is consistent with the electron atom collision frequency’s dependence on pressure. Kuzuya et al. have taken plasma images at different pressures. They found that the spatial confinement of the plasma becomes stronger with increasing gas pressure. The confining effect produces a denser and hotter plasma which could cause an increase in both the emission period and the emission intensity. At low pressures, owing to the weak confining effect of the plasma by the surrounding gas, the laser-produced plasma expands rapidly and becomes thin, resulting in a decrease in the emission intensity. At moderately high pressures, high-temperature and high-density plasma is generated, and the intensity of the continuous emission spectrum is very high; also, the self-absorption effect takes place to a remarkable extent due to the increase in concentration of the absorbing species surrounding the hot plasma. As a result, one is faced with difficulty in terms of precision and sensitivity. To obtain intense emission spectra free from self-absorption, LIBS measurements should be performed at a moderate pressure range \((50 < P < 500\) torr in air).

The effects of various atmospheres including Ar, air, O\(_2\), N\(_2\), He on LIBS spectra have been studied. The inert gas acts like a buffer gas to prevent rapid oxidation of the free atom in the plasma. Argon breakdown occurred in the plasma at a relatively high pressure. The argon atmosphere can enhance the analytical signal by re-excitation of atoms, resulting from collision with photon-excited argon. LIP in the Ar atmosphere has a higher plasma temperature and longer emission period due to the low thermal conductivity of Ar. The higher plasma temperature in the Ar atmosphere also produces the highest continuum background. The emission characteristics of LIP from the air atmosphere are similar to that from the Ar atmosphere. However, the continuum background is only half of that in the Ar atmosphere. Helium has higher thermal conductivity and higher ionization potential than nitrogen or argon. Hence, it has a high-energy coupling efficiency compared with Ar or air. Therefore, background from a He atmosphere is lower and less sensitive to changes in laser energy and pressure.

### 2.2 Analytical Characteristics

In LIBS, the material in the laser spark is immediately reduced to elemental form, and the resulting atoms are electronically excited due to the high plasma temperature. The characteristic atomic and ionic emissions from the excited species are detected and used for analysis. Owing to the rapid expansion and the subsequent cooling effect, the analytical signal from a laser plasma is time dependent. In the first several microseconds, the continuum background emission dominates. As the plasma cools down, the background emission decreases
significantly and ionic and atomic line signals become the dominant spectral feature. Most LIBS work is performed with time-resolved measurements to avoid the strong continuum background in the initial plasma and to improve the S/B ratio. Kagawa and Yokoi found that the LIP consists of two distinct regions when using an N₂ laser (337.1 nm) – primary plasma acts as an initial explosion energy source and emits an intense continuous emission background for a short time just above the surface of the target; secondary plasma expands with time around the primary plasma. It is formed by excitation from the shock wave and by emitting sharp atomic emission lines with a low background signal. The shock wave travels in the opposite direction of the laser beam, to heat and ionize the gas it passes through. The gas is then more capable of absorbing laser radiation and becomes the heat source to maintain the shock wave in the initial stage. Studies have shown that emissions from secondary plasma are suitable for quantitative analysis. Several researchers have proposed the use of time-integrated LIBS in the secondary plasma for quantitative elemental measurement. Time-integrated LIBS does not require the expensive gated detection system necessary in time-resolved LIBS. Therefore, the cost of the LIBS system can be greatly reduced.

The theoretical analysis of emission lines assumes LTE in the environment. Assuming LTE, the plasma temperature and electron density can be used to understand the atomization, ionization, and excitation processes occurring in the plasma. The plasma temperature can be determined from Equation (2) using the relative intensity of two lines of a given atomic species. If more than two lines of intensities are available, the temperature can also be extracted through the Boltzmann plot method. The concentration ratio can be determined from the intensity of the analytical lines free from spectral interference. For this measurement, analyte lines with similar upper energies should be chosen to compensate for changes in the plasma. The degree of ionization for different elements can be quite large, therefore the degree of ionization will also need to be considered in the calculation of the concentration ratio.

The interaction of the laser pulse with the sample strongly influences plasma properties. In a gas, most laser energy is used to excite the sample. But in liquids and solids a lot of laser energy goes into material vaporization and less energy is left for excitation. Therefore, the optimum experimental conditions for different samples will be different. Some characteristics of LIBS in different phases of samples are discussed below.

2.2.1 Solid Sample
Both conducting and nonconducting solid samples can be analyzed with LIBS. As the laser beam is focused on the sample surface, the sample material absorbs the laser energy to melt and vaporize the target material. The vapor absorbs more energy and forms a high temperature plasma near the surface. The plasma expands into the atmosphere and transfers its energy to the atmosphere. Highly ionized emission lines can be found close to the target surface, whereas singly ionized and neutral emissions appear further away from the surface. As the laser breakdown threshold is lower in solids than in gas, generally less laser energy is needed for solid-sample measurement. The analyte signal is proportional to the laser energy. Increasing the laser energy could cause ambient gas breakdown prior to the formation of metal vapor plasma. This will influence the laser energy coupling to the target and result in a weak analyte signal, because laser energy is used to vaporize and excite the sample rather than to produce air breakdown. A lower plasma temperature is expected for solid-sample measurement. The short-wavelength laser seems to give a greater ablated mass and better S/B ratio. Study has also shown that the relatively colder plasma generated with a short-wavelength laser can result in incomplete atomization and, hence, a poorer analytical result. The interaction of the laser spark with the sample surface causes nanograms of material to be ablated from the surface and form a small crater on the sample surface. The size of the crater is independent of the sample material, but the depth of the crater depends on the type of matrix and is proportional to the thermal conductivity of the sample material.

Hwang et al. used an ArF excimer laser to study laser energy with emission intensity for four metals (Cu, Zn, Ni alloy, and iron alloy). They compared the experimental data with calculated mass removal $m(t)$ which was derived based on a heat conduction mechanism (Equation 5):

$$m(t) = AIt + Bt^{3/2}$$  (5)

where $I$ is the laser irradiance and $A$ and $B$ are the constants determined by the thermal properties of the metal.

Good correlation between the experimentally obtained emission intensity and theoretically calculated mass using the above equation was found for the four metals studied. Experiment shows that the LIBS signal also changes with time when the same location is sampled by the laser pulse (Figure 3). As the laser continuously samples at the same location, the crater size changes and results in a time-varied LIBS signal. To obtain reproducible results, LIBS measurements should be taken after a certain ablation time when the signal is at a more stable level. If possible, the sample should also be slowly translated to ensure that the measurement is performed at a new spot each time.

Surface properties can affect the material ablated from the sample, and therefore can affect LIBS precision and
2.2.2 Liquid Samples

The physical properties of the laser spark in liquids have been studied extensively.\(^{(31)}\) The application of LIBS in liquid analysis was not demonstrated until 1984.\(^{(32)}\) LIBS for liquid-phase analysis can be performed by focusing the laser beam in the bulk liquid or at the surface. Bulk liquid analysis does not require a stable free surface. It avoids the liquid splashing due to the plasma shock wave propagated through the liquid surface which can cause the contamination of the optical components and shot-to-shot signal fluctuation. However, it requires a liquid that is transparent at the wavelength of the laser and the analyte line. When plasma forms inside a liquid, the atomic and ionic emissions from the constituent elements have relatively short lifetimes compared to the spark in air. Also, emissions from the background continuum, neutral and ionized atoms, and simple molecules appear simultaneously. Therefore, the time-resolved measurement cannot effectively eliminate spectral interferences for liquid analysis. However, a significant improvement of S/B for liquid analysis has been demonstrated with a shorter laser wavelength.\(^{(33)}\) Studies of the effect of laser wavelength on the analysis of liquid using LIBS found that a 532 nm laser beam produced a very strong continuum background interfering with the analyte signal, whereas a 193 nm laser beam produced several orders of magnitude higher analyte signal with a relatively dimmer plasma. The improvement on S/B with a short-wavelength laser is because the LIP process became less thermal, and the optical energy is effectively coupled into the target rather than heating up the plasma shield. This avoids violent ablation while the liquid is absorbing the laser energy, and makes single-shot measurement in liquids possible.

The LIBS detection limit in liquids is only sufficient for measurement of the minor and major species. To improve the LIBS detection limit in liquids, several techniques were tested. A technique utilizing two sequential laser pulses to sample the same volume of liquid has shown significant improvements in the detection limits of some elements in liquids. The two sparks are spatially overlapped and temporally separated. The first spark vaporizes the liquid, producing a gaseous cavity containing species characteristic of the liquid. The second spark excites the vaporized material. The detection limit for boron had been improved 15 times by using the sequential spark method.\(^{(32)}\) However, the sensitivity of Li and
Na did not change with this double spark technique, and it is believed that these elements are fully excited by the single spark.

The detection limits of some elements were improved by forming the laser spark on the surface of the liquid, which produced a higher-temperature spark than the spark formed in the bulk liquid. Uranium could be detected in the bulk liquid at 300 g L\(^{-1}\), whereas a detection limit of 0.1 g L\(^{-1}\) can be achieved with the surface excitation technique.\(^{34}\)

For LIBS measurements in liquids, it is also useful to send the laser beam through the side or the bottom of the mixture, to avoid optical interference from liquid splashing and the gas bubbles liberated as the liquid–gas surface.\(^{32}\) Long spectral averaging should be used to improve LIBS shot-to-shot fluctuation in liquid application.

### 2.2.3 Gas Samples

LIP in gas has been studied extensively.\(^{6}\) The breakdown in the atmospheric pressure gases were in the cascade ionization mechanism where the threshold was proportional to the ionization potential of the gas and inversely proportional to the collision frequency. The laser breakdown threshold depends on laser wavelength, gas pressure, and laser energy. The experimentally obtained breakdown threshold is much less than that predicted by theory, because the presence of aerosols causes aerosol-induced breakdown. The mechanism of aerosol breakdown is not fully understood, but experimental data shows that aerosols, acting as seeds, can significantly lower the breakdown threshold of clean gas. Smith and Brown have shown that aerosol-induced breakdown has a strong dependency on gas species, pressure, and laser wavelength, similar to that predicted for a collision-induced process.\(^{35}\) They also demonstrated that, in the presence of micron-sized aerosols and impurity particles, the breakdown threshold in a gas is inversely proportional to the size of the focused laser beam. This is because the probability of finding a particle of sufficient size within the focal volume is higher.

Typically, laser-induced air breakdown has a plasma temperature of 20000 K and an electron density of \(10^{17} \text{–} 10^{18} \text{cm}^{-3}\) after the plasma is formed. Emission from CN can be observed from LIP in air. The CN is produced from the reaction between C and N, produced in the spark. The intensity of the CN bands depends on the concentration of a C-containing compound in the gas stream. The elements in the spectral region covered by the CN bond have less sensitivity due to this spectral interference.

LIBS can directly measure a gas sample, eliminating the need of sample preparation. Cremers and Radziemski detected Cl and F in air with detection limits of 80 ng and 2000 ng respectively.\(^{36}\) They found that the absolute detection limit for Cl and F can be improved to 3 ng in an He atmosphere. Radziemski et al. used LIBS to detect Be, Na, P, As, and Hg in air.\(^{37}\) Owing to the small sample volume and possible sample inhomogeneity, the measurement precision in a gas sample is generally poor. Various sized particulates in the gas can cause breakdown to occur at different locations along the axis of the laser beam, and this leads to significant signal variation. The variables affecting the characteristics of LIBS spectra in a gas include particle size, gas pressure, temperature, and laser energy. For quantitative measurements, the calibration procedure should keep these variables as close to the measurement conditions as possible.

### 2.3 Interference

Three types of interferences – self-absorption, spectral overlap (spectral line interference, band interference), and matrix effect (chemical interferences) – are generally encountered in LIBS. Self-absorption occurs when the emission from the hotter region is absorbed by cool atoms surrounded by the high-temperature core of the laser plasma. To avoid the problems with self-absorption, resonance lines should only be used for the measurement of trace elements.

Spectral interference due to line overlap is very common, because the resolution depends upon the monochromator used. Care should be taken to avoid spectral interference lines in the analysis. Emission lines are often superimposed on bands emitted by oxides and other molecular species from air or samples. A background correction for band emission is necessary. The absolute intensity of an analyte line can be obtained by subtracting the peak height from the background signal near the analyte line.

The physical and chemical properties of the sample can affect the plasma composition, a phenomenon known as the matrix effect. The matrix effect can result in the sample being ablated differently from the target sample. This was found in measurements of Zn–Cu alloy foil, for which the Zn/Cu weight ratio was found to be as much as 30% greater than that of the sample (independent of the laser energy, number of laser pulses, and linear to the weight ratio of the sample).\(^{41}\) The matrix effect may be due to the incomplete vaporization (atomization) in LIP. Some researchers suggest including a correction factor in the calibration to take into account the matrix effect.

Sometimes interferences from the same element, dissociated from the molecular species in the atmosphere, can cause a higher inferred concentration. In carbon measurement in air, atmospheric CO\(_2\) near the laser
spark is dissociated, and the resulting carbon atoms are added to those arising from the sample. This leads to a higher inferred carbon concentration. To improve the carbon measurement, LIBS has to be performed in a CO₂-free environment. Aguilera et al. have shown that, for carbon measurement in steel, a nitrogen environment effectively eliminates the residual carbon emission.\(^{38}\)

Other types of interference include signal fluctuations due to particles and detector saturation by a very intense signal. In addition to experimental precaution, certain data selection schematics are sometimes needed to exclude some distorted data. The resonances lines are not often the most suitable lines for quantitative analysis, because they are susceptible to self-absorption. Reducing the pressure of the surrounding atmosphere can minimize the occurrence of self-reversed emission.

As the plasma condition fluctuates from pulse to pulse, and it is difficult to control the variables associated with the excitation condition, an internal standard is generally employed to compensate for the effects of laser plasma variation. An internal standard is a major element in the sample. The concentration of the internal standard is known and always the same. An emission line of the internal standard is selected for measuring the relative concentration of the other elements in the samples using the intensity ratio of the analyte line to the standard line. The internal standard line is chosen so that the excitation energies and partition functions of the analyte and internal standard lines are similarly matched, so as to compensate for changes in the plasma. To minimize the effects of the spectral response of the detection system at different spectral regions, the analyte lines and the standard line should be chosen from the same spectral region. The matrix effect, which causes the sample to be ablated differently from the target sample, cannot be corrected with the internal standard. The requirements to perform a matrix-independent measurement by using internal standard are: complete atomization of particles and droplets in an LTE microplasma; and the intensity ratios of line pairs of different elements with approximately the same excitation energies must be dependent only on the concentration ratios in different matrices.

### 3 EXPERIMENTAL TECHNIQUES

#### 3.1 Experimental Methods

Since the first report of a laser-induced spark with a ruby laser by Maker, Terhune, and Savage in 1963,\(^{39}\) a variety of experimental methods have been developed to perform basic research and practical applications. The development of LIBS is closely related to the development of laser techniques. From the early ruby and CO₂ lasers to more recently and widely used Nd:YAG and excimer lasers, more powerful, reliable, and compact laser systems have been used to perform LIBS. LIBS development is also based on the development of detectors, fiber optics, and computer technology. New detectors such as the intensified charge coupled device (ICCD) have replaced the old photomultiplier tube (PMT) and photodiode array, and have achieved much faster time responses and higher S/N values. Recent computer technology advances have enabled LIBS to perform real-time operations, which have enhanced its capability as a method for process monitor and control.

In 1982, Sandia National Laboratories-Livermore reported a time-integrated LIBS system for combustion applications with a Q-switched CO₂ transversely excited atmospheric pressure (TEA) laser.\(^{40}\) The laser generates a series of mode-locked pulses separated by 7.8 ns extending over about 1 µs with total energy about 1.7 J at a wavelength of 10.5 µm. The beam is expanded, then focused at the point of interest. The emission from the induced spark is collected in the direction perpendicular to the beam and coupled to a 1 m spectrometer with proper optics. An intensified diode array was used to record the LIBS spectrum.

Almost at the same time, L.J. Radziemski et al. introduced a time-resolved technique to record the LIBS signal.\(^{37,41,42}\) As the emission characteristics of the induced spark vary with time, the time-resolved measurement can temporally separate the emissions from different species in the induced plasma. This technique has been successfully used to maximize the S/B and to minimize the spectral interferences between atoms of different ionization stages as well as between atoms and molecules. In the time-resolved detection, the detector was only exposed to light during a specified gate time which is controlled by a time gate pulser. The gate pulse signal was delayed with respect to the laser pulse with a width of 200 ns to several µs. It provides a high voltage to the detector intensifier to only record the signal during the time of the gate. Figure 4 is a diagram of their system for time-resolved LIBS measurement.\(^{37}\) An Nd : YAG laser operated at 1.064 µm (pulse width 10 ns and pulse energy 100–300 mJ) was used to generate the laser spark. The array detector, consisting of 1024 diodes in 25.4 mm, was controlled by a multichannel analyzer to record LIBS spectra. The sample was delivered by a nebulizer/heat-chamber system into a six-arm crossed-sample chamber where the laser beam, observation direction, and the sample flow are perpendicular to each other. With a different gate time, the ionic and neutral lines of nitrogen were successfully observed. This time-resolved technique was later adopted by many researchers due to its ability to obtain a better S/B.
In 1984, D.A. Cremers et al. reported two experimental methods for LIBS measurements of liquids. The two methods are repetitive single spark (RSS) and repetitive spark pair (RSP). In RSS, an Nd:YAG laser operated at 1.064 µm was focused into the liquid by a pair of 5 cm focal length lenses. The beam was focused into the cell through a quartz window on the bottom side. The cell was constructed of Teflon and its volume was 20 cm³. A small, intense, reproducible spark was obtained when the beam was focused in the liquid very close to the input window (within 2–5 mm). A strong pressure generated by the spark was observed. The spark light was collected at right angles to the laser beam. Either a PMT with boxcar averager or a photodiode array with multichannel analyzer was used. The signal was temporally resolved and averaged over many shots. In RSP, two Nd:YAG lasers were employed to generate a pair of sparks separated in time by about 18 µs. The beams from the two lasers were spatially superimposed with a 50%T:50%R beam splitter (R = reflection and T = transmission). The second spark is generated inside the gaseous cavity formed after the first spark. The signal intensity of some species was found to be enhanced significantly with the RSP method.

Cremers and Radziemski carried out an experiment using the long-spark technique for direct detection of beryllium on the filter. A long spark was generated by focusing the beam of a pulsed and Q-switched Nd:YAG laser on the surface with a cylindrical lens of 75 mm focal length. Laser energy of 125 mJ per pulse was used to ensure spark stability. The footprint of the spark on the surface was about 0.1 mm wide and 4–8 mm long, depending on the angle of incidence of the laser beam on the filter. The emission from the induced plasma was collected by another lens in the perpendicular direction and analyzed by a monochromator tuned to the wavelength of 313.042/313.107 nm which is the doublet of Be⁺. The spectrally resolved light was detected by a PMT. The signal was time-resolved and averaged with a boxcar average.

Mason and Goldberg produced a laser spark in a pulsed magnetic field to characterize the effects of a magnetic field on plasma atomization, excitation, and ionization. Both emission and absorption spectroscopy were performed. An eight-turn coil was wound on a 1 inch outside diameter polycarbonate tube and a high-voltage capacitive discharge source was used to generate the pulsed magnetic field. A pulsed hollow cathode lamp was used for the absorbance measurement. The hollow cathode lamp was triggered before the formation of the laser plasma and kept active for over 300 µs in order to output a stable emission. The light was collimated by a lens and, after passing through the coil,
was focused by another lens onto the entrance slit of the monochromator. The emission characteristics were found to have significant radial compression and axial expansion of the laser induced plasma.

In 1987 Cremers used a fused silica incoherent fiber bundle instead of a lens to collect the emission from the laser spark. The cable was 1 m in length and 3 mm in diameter. One end of the cable was positioned next to the focusing lens (50 cm focal length) and the other end of the cable was positioned up against the entrance slit of a spectrograph. When the fiber optic cable was positioned 55 cm from the spark, the light collected by the fiber optic bundle was equivalent to that collected by a lens with an \( f \) number of 183. Because of the large acceptance angle of fiber optics, light from a wide angle range will be collected by the fiber and is not changed significantly at the output end. This fiber collection technique is suitable for field measurements because it is insensitive to the spark position changes. Schechter and Valery Bulatov have developed a fine technique using an optical fiber. A multiple optic fiber system, with each fiber pointing at a different region of the spark, was used in their measurement. The light from a different fiber was fed into a computerized imaging spectrometer which was attached to an ICCD detector. The fluctuation in the spark was compensated for by observing different elements at a different region in the spark.

LIBS is a useful technique for in situ field measurements. However, most experimental methods introduced previously are laboratory systems and may not be well suited to field measurements. A field system usually requires minimal optical access to the test facility and minimal on-site alignment. In 1994, researchers from Sandia National Laboratory completed a field demonstration of their prototype system to monitor metals emissions at Clemson University’s Vitrification Facility. The main feature of the system was a mirror with a hole at the center to allow the laser beam to pass and to reflect the emission signal from the laser spark (Figure 5). The frequency-doubled Q-switched Nd:YAG laser beam (532 nm) was expanded and collimated to pass through the hole in the mirror. The beam was focused in the effluent stream and produced the spark. The same lens was also used to collect and collimate emission from the spark. The lens was mounted at the end of a probe inserted into the test facility through an optical port. The collected light was reflected by the mirror to turn 90° and forward to other optics coupled to the fiber optic bundle. The fiber optic bundle was connected to the spectrometer and detector. This configuration allowed excitation and detection to be performed collinearly and, therefore, only one optical port was used for access and measurement.

Another approach to backwards LIBS detection was developed at the Diagnostic Instrumentation and Analysis Laboratory of Mississippi State University (Figure 6). The frequency-doubled Q-switched Nd-YAG laser beam was reflected at a harmonic separator to remove its fundamental beam. The 532 nm beam was then reflected to the probe lens through a dichroic mirror that reflects 532 nm and transmits other wavelengths. The beam was focused in the off-gas stream to produce the breakdown. The same lens was also used to collect and collimate emission from the plasma. The LIBS signal was transmitted through the dichroic mirror and coupled to the fiber optic bundle with lenses. The fiber optic bundle was connected to the spectrometer and detector.

![Diagram of a LIBS system using a mirror with a hole for backward detection. (Reproduced from L.W. Peng et al. Process Control and Quality, 7, 39–49 (1995), by permission of VSP International Science Publishers.)](image-url)
The rectangular output of the fiber bundle worked as an entrance slit for the spectrometer. This optical configuration, which requires only one port, also allows collinear excitation and detection. It is suitable for real-time measurement in off-gases.

Due to the low breakdown threshold of the optical fiber, optical fibers in early LIBS work were limited to delivering the emission to the detection system. It is now possible to use optical fibers to deliver the laser beam in LIBS applications. Marquardt et al. have recently developed a microprobe for LIBS and Raman measurements using an imaging optical fiber. The microprobe has five separate optical fibers. One 1 mm core diameter silica–silica-clad multimode fiber was used to deliver the Q-switched Nd:YAG laser beam (1.064 µm) for LIBS excitation. A 12 mm focal length lens near the fiber collimated the exited laser beam and a 6.4 mm focal length lens focused the laser beam on the sample. These two lenses were also used to collect spark light and couple the light to another 1 mm core diameter hard-clad fiber which coupled to the spectograph at another end. The Nd:YAG laser beam delivery fiber was also used to deliver a He–Ne beam to indicate the region of interest on the sample. One image-guide fiber was coupled to a video camera to provide video monitoring while the probe was positioned and aligned for analyzing specific sites on the sample (granite). An ICCD detector was used and operated in gated mode.

### 3.2 Calibration Methods

For practical applications, the measured emission intensities need to be related to the relative or absolute elemental concentration. The system response must be calibrated for a certain measurement. Calibration is the most difficult issue in the development of LIBS, especially for field measurements. LIBS is an atomic emission spectroscopy. In addition to variables related to emission spectra, several other variables greatly affect the intensity of the LIBS signal: the fluctuation of incident laser energy; the size and density of particles and associated matrix effects in the gas flow; the location of the focus point for solid and liquid samples; and the surface feature and the history of ablation by laser shots for solid samples. For on-site measurement, LIBS is considered as a nonsampling technique. However, this implies an extra difficulty for calibration.

For solid sampling, a standard sample can usually be pressed from well-mixed powders. Ernst et al. determined the copper concentration in steel using LIBS. They prepared cylindrical calibration samples using a hot isostatic press process. The flat surfaces of the sample were polished with a soft polishing wheel and cleaned. Eleven samples containing from 0.01% to 5.00% copper were used to obtain a quadratic calibration curve. To reduce the effect of some variables, the intensity ratio of Cu/Fe was used, instead of Cu intensity, to infer the calibration curve against the Cu concentration. For some solid samples, instead of pressing, well-mixed powders can be placed in a furnace to be melted and then frozen.

For gas-phase sampling, a nebulizer is widely used to produce a dry aerosol from a solution of standard reference materials. During a United States Environmental Protection Agency (USEPA) metal CEM test in 1996, a pneumatic nebulizer was used to produce an aerosol flow containing certain concentrations of metal. The nebulizer was enclosed in a separate cell and was inserted into the optical path when the calibration was required.
During the same CEM test, an on-site calibration was performed at the Rotary Kiln Incinerator Simulator. An ultrasonic nebulizer (USN) was used to generate a dry metal aerosol from the standard solution which was pumped into the USN with a peristaltic pump. The aerosol was brought to the gas stream through a sample injection probe. The probe tube was mounted on the opposing port against the optical probe across the gas stream. The laser beam was focused 2 cm above the end of the injection probe.

In some cases, if the absolute concentration calibration is too difficult to obtain, the relative concentration may be considered. According to Equation (2), relative concentration can be inferred by fit or by intensity comparisons of two or more different elements in one LIBS spectrum. In addition to the spectroscopic constants, the plasma temperature and degree of ionization are required to perform this calculation. However, these two parameters are not easily determined accurately. An alternative approach to obtaining the relative concentration was the use of reference line intensity information from the National Institute of Standards and Technology (NIST) collections to perform spectral fitting. However, the excitation condition need to be checked for this simple method because the intensities in these reference collections are obtained under conditions which differ considerably from induced plasma.

The techniques for LIBS calibration, especially for field calibration, lags behind the development of LIBS itself. Scientists are still working to solve this problem.

4 ENVIRONMENTAL APPLICATIONS

LIBS has the capability to perform rapid, on-site analysis in harsh environments. It can significantly reduce the time and costs associated with sample preparation required by conventional analytical techniques and is therefore a promising technique for environmental monitoring and process control. LIBS has been applied to many environmental situations. The major interests here are applications in environmental monitoring and in industrial process control. Other application areas, e.g., clinical, metals, etc., are discussed elsewhere.

4.1 Off-gas Emission

The detection of trace metals in the off-gas from waste processing is very important for public health. Conventional analytical techniques require sending a sample to a laboratory for analysis. LIBS can perform in situ off-gas measurement by focusing the laser beam on the gas stream through a window and collecting the signal through an optical fiber. Radziemski and Cremers applied LIBS to the analysis of effluent gases from a prototype fixed-bed coal-gasifier at the Department of Energy Morgantown Energy Technology Center. They demonstrated that LIBS had the capability for near real-time monitoring of the concentrations of major and minor species in the off-gas emission. Neuhauser et al. tested their on-line Pb aerosol detection system with aerosol diameters between 10 and 800 nm. A detection limit of 155 µg m⁻³ was found. Singh et al. have demonstrated LIBS as a process monitor and control tool for waste remediation. They monitored the toxic metals from three plasma-torch test facilities and proved that LIBS can be integrated with a torch-control system to minimize toxic metal emission during plasma-torch waste remediation.

To use LIBS as a CEM requires the quantitative trace-level determination of toxic metals. The challenges here are to overcome the problems of this technique related to poor detection sensitivity for some elements, limited accuracy and precision, and difficulty of calibration for in situ analysis. With a sensitive ICCD detector and properly selected experimental set-up, the sensitivity and precision has been greatly improved. However, on-line calibration is still a big problem for CEM-type applications due to difficulties of introducing known amount samples into the off-gas system.

Singh et al. investigated the possibility of using metal hydrides to calibrate metals in off-gas emissions. They used a static sample cell to perform LIBS experiments on metal hydrides and found the LIBS signal to be affected by gas composition, gas pressure, and laser intensity. They also found that the LIBS signal intensity for metal hydrides changes with time. The time at which the signal reaches its peak also depends on the concentration of the sample. Therefore the selection of different time periods for the LIBS measurement will be critical for LIBS calibration. They suggested that a flowing metal hydride sample cell system might solve some of the problems related to the static system they used.

Detection of Hg in off-gas emission has been reported by several researchers. Lazzari et al. performed LIBS to detect Hg in air in a laboratory. The Hg vapor was successively diluted in a chamber, and a Nd:glass laser (1064 nm, 180 mJ) was used to produce plasma in the Hg vapor. They reported a very low detection limit of 42 µg m⁻³ for Hg using the Hg 253.7 line. Singh et al. used an USN to generate a known concentration of metal aerosol in a sample cell and found the minimum detectable Hg level to be approximately one order higher than that reported by Lazzari et al. The reported Hg detection limit with a pneumatic nebulizer is consistent with the result with an USN. The reason for a higher Hg detection limit with a nebulizer system is unclear. One possible explanation is that the aerosol-induced
breakdown might cause incomplete atomization of larger particles in the colder region of the plasma and this results in a higher Hg detection limit.

The laboratory-tested calibration technique is successful for simulated effluent in a sample cell using an aerosol generator. However, it cannot be directly applied to samples from the practical environment due to difficulties in reproducing the plasma conditions under quite different sampling conditions (i.e., particle size, gas flow, temperature, pressure, etc.). As a result of the difficulties in injecting a known amount of sample into a gas stream, researchers are now exploring the possibility of using an internal reference for self-calibration. The internal reference has to be a major species in the gas medium. The concentrations of the internal reference must be known to an accuracy below 10%. This calibration method is intended for compensating plasma condition changes due to the variation of gas stream conditions or laser pulse-to-pulse fluctuations. Therefore, the plasma temperature has to be inferred from the reference lines. The intensity ratio of the analyte line and the reference line are corrected based on the inferred plasma temperature. Loge has tested this calibration procedure for LIBS CEM using $N_2^+$ lines to determine plasma temperature and to monitor the changes in the plasma condition. The observed emission line intensities were adjusted based on the inferred plasma temperature, and the concentration was extracted from the plasma temperature-corrected calibration curve. However, the plasma condition is not only characterized by plasma temperature. Electron density can also affect the degree of ionization of the probed atoms and hence the signal of the neutral or ion line. Furthermore, this calibration relies on the plasma temperature extracted from the intensity ratio of two emission lines, which is known to be an inaccurate method for plasma-temperature determination. This calibration might be suitable for LTE conditions in which electron density and plasma temperature are not significantly different from the calibration condition. However, the success of this internal calibration method will greatly depend on the plasma characteristics and matrix effect.

LIBS has low sensitivity for some elements in off-gas measurements because of its small sample volume. Hahn et al. developed a technique based on random sampling and conditional analysis to solve the problem associated with finite sample volume and size distribution of the target metal. They compared Monte Carlo simulation with the experimental results and claimed considerable enhancement with this technique for low metal concentrations where only a few single-shot spectra contained the desired metal emission. This calibration technique seems promising; however, more tests are required to prove its validity for different sampling conditions.

LIBS has been tested as a multimetal CEM. Using concentrations as specified by the Resource Conservation and Recovery Act (RCRA), metals were measured and the results compared with the USEPA’s reference method. A relative precision of 50% and a relative accuracy (RA) of 78% or better were obtained from these tests. The rapid sampling rate and potential for metal CEM are demonstrated in this test. However, the sensitivity and accuracy for certain toxic metals will need to be further improved before LIBS can be accepted as a metal CEM by the USEPA.

4.2 Metal and Glass

Kurniawan et al. have applied LIBS to the elemental analysis of glass. They found the detection limits are much lower than those usually required for glass with low surrounding pressure (1–5 Torr). In addition, light elements (such as Li and B) that are usually difficult to observe by X-ray fluorescence were also successfully detected with a detection limit less than 10 ppb. Thiem et al. performed LIBS measurements on alloys in an ultrahigh vacuum (<5 × 10⁻⁷ Torr). They found the background signal is significantly reduced in comparison to that from an atmospheric environment. This makes a simultaneous, multielement analysis in very complex solid samples possible. They obtained calibrations for Al, Fe, Cu, Ni, and Zn using a standard reference material and found the detection limit to be matrix dependent. Absolute detection limits were estimated to be in the 20–200 µg g⁻¹ range for the above elements. Sabsabi and Cielo made quantitative analyses of aluminum alloys with LIBS. To find the optimum condition for LIBS analysis, they first studied laser plasma characterization by extracting plasma temperature and electron density with Fe and Al⁺ lines, respectively. They found plasma temperatures are close to a constant within experimental uncertainty at 10 µs delay and 10 µs gate width with different concentrations of Mg in aluminum alloys. Calibration curves for Mg, Mn, Cu, and Si were constructed under this optimum experimental condition. The Mg calibration based on the 285.2 nm resonance line shows problems of self-absorption at higher concentrations, whereas the calibration based on nonresonance 518.36 nm and 517.27 nm Mg lines is linear for the same concentration range. The precision and detection limits for LIBS analysis of aluminum alloy were calculated based on the calibration data. They found a relative standard deviation (RSD) of better than 6% and detection limits better than 15 ppm for all the elements studied.

The current process for molten steel analysis includes collecting a molten sample, cooling it, and then transporting it to a nearby analytical laboratory for analysis. It is a time- and labor-intensive process. The hot melt composition might change due to vaporization of the more
volatile components during this period. Also, compositional fluctuations cannot be effectively monitored with the current analysis method. LIBS has the capability of performing on-line measurements, which can reduce the data processing time and reduce the cost for the steel industry.

Argagon et al. have demonstrated the application of LIBS to molten steel.\(^{(71)}\) To measure the carbon content they used an argon atmosphere to reduce carbon emission from dissociated CO or CO\(_2\). As the composition of the molten surface may not represent the bulk melt, an Ar jet was applied on the surface of molten steel to measure the bulk concentration during the measurement. A C/Fe detection limit of 250 ppm with a RSD of 6% was found. Lorenzen et al. developed an on-line monitor for molten steel.\(^{(59)}\) Elemental concentrations were determined based on calibration of the intensity ratio of an analyte line and a reference line versus elemental concentration. To ensure measurement accuracy, they also monitored the plasma condition using the intensity ratio of an atomic/ionic line pair. When a change in the plasma condition was detected, a proper correction factor was applied to the calibration curve. Paksy et al. also performed LIBS on the surface of a molten alloy using an Nd: YAG laser.\(^{(72)}\) They compared the measurement with argon and air atmospheres and found that the Ar atmosphere prevents surface oxidation and gave a higher S/B with good precision for a relative intensity measurement. Detection limits for Si/Fe, Mn/Fe, Cr/Fe, Si/Al, and Mn/Al were found to be 10 ppm, 50 ppm, 40 ppm, 600 ppm, and 70 ppm respectively.

The application of LIBS to solid/molten materials is very promising. However, problems such as matrix effects (selective vaporization), sensitivity for all the element of interest, calibration, precision, and accuracy still need to be solved for quantitative measurement. Although it cannot provide the high accuracy and precision of laboratory-based methods, it has great potential as a process control monitor in the steel and glass industries by providing rapid, semiquantitative composition measurements in a remote location.

### 4.3 Soil, Concrete, and Paint

The detection of contaminated soil and concrete is another challenging area for LIBS. Yamamoto et al.\(^{(73)}\) have used a portable LIBS system to detect toxic metals in soil, finding Ba, Be, Pb, and Sr in soil with detection limits of 265, 9.3, 298, and 42 ppm, respectively. Cremers et al. have detected Ba and Cr in soil using an optical fiber probe.\(^{(74)}\) Limits of detection (LODs) of 26 ppm and 50 ppm were found for Ba and Cr, respectively. Eppler et al. have studied the matrix effect in soil. They found LODs for Pb and Ba in a sand matrix were 17 and 76 ppm (by weight), respectively, with a precision of 7% RSD or less.\(^{(75)}\) In soil, the detection limits were 112 and 63 ppm (w/w) for Pb and Ba, respectively, with 10% RSD precision. The LIBS signal was affected by chemical speciation as well as matrix composition. LIBS accuracy can be degraded if calibrations are not compound and matrix specific. The accuracy of LIBS measurement in soil is affected by many factors. It is presently more suitable as an initial screening of highly contaminated soils to determine the remediation boundary of the contaminated area.

LIBS for detection of lead in contaminated concrete was explored by Pahkhomov et al.\(^{(76)}\) They used a Q-switched Nd: YAG laser (10 Hz) to perform time-resolved LIBS for quantitative measurement of the lead content in concrete. Pb calibrations were obtained for different delay times using the ratio of the integrated emission line of lead (405.78 nm) to an oxygen line (405.59 nm). They found the absolute Pb signal is independent of the laser pulse energy for laser energies between 250 and 400 mJ. Based on analysis of the sensitivity of lead measurements at different delay times, they derived a best Pb detection limit of 10 ppm in concrete at an optimum delay time of 3.0 \(\mu\)s.

Lead in paint is known to be a potential health threat, especially to children. The feasibility of using LIBS to determine Pb in the paint surface has been successfully demonstrated by Yamamoto et al. using a portable LIBS system.\(^{(73)}\) The temporally integrated LIBS signal is recorded with a nongateable charge-coupled device (CCD) detector. Because of the problem of spectral interference associated with the Pb 405.78 nm line, they used a weaker Pb\(^+\) line at 220.35 nm for calibration. They obtained a Pb detection limit of 0.8% (8000 ppm) in paint with an RSD between 23% and 47%. Marquardt et al. used a fiber optics LIBS system to determine Pb in paint.\(^{(52)}\) They used a gate delay of 3.0 \(\mu\)s and gate width of 12.6 \(\mu\)s in the measurements. They reported a LOD of 140 ppm for Pb with a precision of 5–10% using the Pb 405.78 nm line.

### 4.4 Air Sampling Filters

Direct detection of trace element in air with LIBS is very difficult due to its insufficient sensitivity. For trace metals below the LIBS detection limits, an air sample can be collected on a filter which is then subsequently analyzed by LIBS. This method has a lower detection limit and provides a quasi-on-line measurement. Arnold and Cremers have used this technique to determine metal particles on an air damping filter.\(^{(77)}\) They used a cylindrical lens to form a long spark on the filter to increase the sample volume and reduce the filter damage. Using the calibration curve for Tl line at 535.05 nm, a LOD of 40 ng cm\(^{-2}\) for Tl in filter paper was obtained. Later, Yamamoto et al.
determined LODs of 21 ng cm\(^{-2}\) and 5.6 µg cm\(^{-2}\) for Be and Pb on a filter.\(^{75}\) They also noticed that particle size can affect the detection limit for filter analysis. Cremers and Radziemski have measured Be on a filter surface and found that Be particles greater than 10 µm on the filter were not completely vaporized. The particle size dependence of the LIBS signal puts a restriction on LIBS application to air sampling through a filter.\(^{44}\)

### 4.5 Radioactive Materials

LIBS has been used to monitor the level of radioactive elements in a process stream. Wachter and Cremers found a detection limit of 100 ppm for uranium in solution.\(^{34}\) To overcome poor shot-to-shot precision due to small variations in the lens-to-sample distance, they had to average 1600 laser shots for analysis. To investigate the feasibility of applying LIBS to detect radioactive elements, Singh et al. recorded LIBS spectra of U, Pu, and Np in a glove box.\(^{76}\) Emission lines suitable for detection of these radioactive elements were identified. Their preliminary study showed that LIBS is suitable for the measurement of radioactive elements in waste streams. Ernst et al. used LIBS as a tool for detection of radiation embrittlement in a nuclear power plant by determining the Cu concentration in A533b steel.\(^{79}\) As Cu is the key impurity contributing to radiation embrittlement, the Cu concentration in the steel is an indicator of radiation embrittlement and of expected material lifetime. Due to the hazardous environment, a fiber optic delivery system was initially used in the measurement. However, the optical fiber system could not deliver sufficient laser energy for sensitive Cu detection. Copper concentrations between 100 ppm and 5% were later detected using a conventional all-optic beam delivery system. Their measurements demonstrated that LIBS can provide quick, accurate, and remote detection for monitoring the reactor pressure vessel material.

### 5 COMPARISON WITH OTHER SPECTROSCOPY TECHNIQUES

The LIBS technique has several advantages compared to conventional emission methods. In LIBS, a high-energy pulsed laser beam is used to produce atomic emissions from the focal volume. Hence it provides time and spatially resolved measurement. It requires only a small amount of sample and minimal sample preparation. Gated detection with an intensified detection system discriminates the background emission and also improves the detection limit. With properly selected atomic lines, multiple species can be simultaneously monitored in a spectral region. Furthermore, as a laser spark can be generated in a remote location, it has remote monitoring capability. In this section the accuracy of LIBS is compared with some spectroscopic techniques commonly used in the laboratory, such as AAS, ICPAES, and XFS. AAS is used to detect the presence and amount of metal atoms in very dilute solutions. It is widely used in laboratories that analyze the purity of water. The resonant wavelength of choice from a selected spectral lamp passes through the sample vapor. The atomized element absorbs the light energy over time. The concentration is determined through a calibration curve. The sample solution can be atomized by passing an electrical current through a graphite tube which contains the analyte (graphite furnace atomic absorption (AA)) or using a flame to atomize the sample (flame AA). The graphite furnace AA technique often offers about 1000-fold sensitivity improvement as compared with flame AA.

ICPAES measures the intensities of light emitted from each species as they are atomized and perhaps ionized in the plasma. As an AES (atomic emission spectrometry) technique, ICPAES has the capability of simultaneous multielement measurement. Atomization is more complete in the ICP (inductively coupled plasma) system than in the AAS system; therefore, LOD values are generally lower for ICPAES than for AAS. However, because the temperature of ICP is much greater than for AAS, spectral interference tends to be a greater problem for ICPAES than for AAS. The temperature cross-section of the plasma is relatively uniform; as a consequence, self-absorption and self-reversal effects are not encountered.

XFS is a spectroscopic method that is commonly used for solids in which secondary X-ray emission is generated by excitation of a sample with X-rays. The X-rays eject inner-shell electrons. Outer-shell electrons take their place and emit photons in the process. The photon wavelength depends on the energy difference between the outer-shell and inner-shell electron orbitals. The amount of fluorescence is very sample dependent and quantitative analysis requires calibration with standards with a similar matrix. XFS can provide rapid quantitative analysis for various samples. However, XFS is not applicable to light elements (\(M < 10\)) such as Be, B, and Li. As the XFS signal is generated from a significant thickness of sample within which absorption and scattering can occur. It is known to suffer significant disturbance from the matrix which is caused by either absorption from the matrix elements or enhancement by the emission of a matrix element.

#### 5.1 Sample Preparation

Laser plasma is a direct sampling and excitation tool. Only small amounts of samples are used. The laser prepares
ICPAES and LIBS have compared the analysis of Al ores from the NIST by many elements into solution as possible. Thiem and Wolf have used sequential. It is an attractive technique for the analysis (including blanks, standards, and sample) to the plasma furnace) to atomize the sample. The sample preparation procedure for AAS is generally time-consuming which is not conducive to online and in situ measurement.

In ICPAES, the sample may be an aerosol, a thermally generated vapor, or a fine powder. The sample is carried into the hot plasma at the head of the tubes by argon flowing at about 1 L min\(^{-1}\) through the central quartz tube of the ICP torch. Typically, the sample is reduced to a solution that is nebulized into the ICP system. An autosampler is frequently used to supply solutions (including blanks, standards, and sample) to the plasma sequentially. It is an attractive technique for the analysis of geological material due to its multielement capability. However, samples need to be dissolved prior to analysis. Various chemical schemes are necessary to dissolve as many elements into solution as possible. Thiern and Wolf have compared the analysis of Al ores from the NIST by ICPAES and LIBS. In ICP measurements, the powder samples are first dried in an oven at 140 °C for 2 h. A specific weight of dried sample is then digested with a mixture of concentrated HCl and deionized water in a digestion flask at 90 °C overnight. The digested samples are then put into a volumetric flask for analysis. When using LIBS to analyze the same type of sample, a small amount of sample was compressed into a disk. The sample attached to a sample translation device is then placed into the sampling chamber. The LIBS measurement started after the sampling chamber was evacuated to about 1 mtorr. The required sample preparation time (including time required to pump down the sampling chamber) for LIBS analysis is less than one hour which is much shorter than that required for an ICP measurement.

XFS can be used to analyze a variety of samples. Liquid samples, from water to oil, require essentially no preparation. Many solid samples, if homogeneous, can be machined to the proper shape and run directly. Inhomogeneous samples, such as ores and biological materials, must be pulverized or fused. Then the homogenized material can be dissolved for analysis as a liquid sample, pressed into pellet form, or cast as a glass-like solid. XFS can also be used for the analysis of atmosphere pollutants. The air sample is first collected through a stack consisting of micropore filters and is then analyzed by XFS directly. Although XFS has direct sampling capability, it suffers more severe matrix effects with direct sampling than does LIBS. Also, XFS does not have remote analysis capability, whereas LIBS can use optical fibers to perform remote measurements.

Comparing LIBS with ICP, AAS, and XFS, LIBS and XFS require minimum sample preparation. AA and ICP require destructive and relatively tedious and time-consuming pretreatment of the samples, which is likely to introduce uncontrollable error in the measurements.

### 5.2 Sampling Rate

LIBS is an optical emission based-technique. It can perform multielement measurements. Generally LIBS can produce useful results in 3–60 s. The sampling rate depends on the laser repetition rate and sample concentration. XFS spectra are relatively simple and the technique is nondestructive. The speed (1–10 min) and convenience of the procedure permits multielement analyses to be completed in a few minutes. ICP and AAS can have a sampling time of less than 1 min. However, sample preparation often takes several hours. It takes minutes to hours for complete sample analysis.

### 5.3 Detection Limit

The detection limit is the minimum concentration that can in principle be measured. It is generally defined as the concentration that produces a signal three times larger than the SD of the background. As multielement techniques, LIBS, ICPAES, and XFS all rely on being able to resolve spectral signals unique to each element. When the signals of some elements are very strong, they start to interfere with weaker signals from the other elements, and it may be difficult to achieve the optimum detection limits. LIBS has poorer sensitivity in gas measurements due to the low concentration and small laser microplasma. Typical LODs for LIBS are in the ppm to percentage range. For ICPAES, detection limits for most elements are of the order of 10 ppb.

XFS is generally less sensitive than the various optical methods. It offers LODs from a few ppm to the percentage range. In AAS, the amount of light that is absorbed by the sample is directly proportional to the concentration of the ground state element of interest in that aspirated sample. Some samples may have matrix, chemical, and/or ionization interferences. When recognized, each interference can usually be controlled to yield meaningful
sample analysis. Detection limits ranging from around $3 \times 10^{-4}$ ppm to 20 ppm are observed for various metallic elements using flame AA. Graphite furnace atomic absorption spectrometry (GFAAS) often reduces this limit by a factor of 10–1000.

This direct comparison of LIBS detection limits with other analytical techniques is unrealistic because of the different samples used. In general, LIBS still cannot match the detection limits of most conventional analytical techniques in most cases. However, its ability to directly analyze samples without cumbersome sample preparation has led to its promising application in practical field determinations of elements for environment and industrial samples.

5.4 Accuracy and Precision

Precision and accuracy are generally used to determine the merit of a measurement technique. Precision is the measure of the degree of reproducibility of a measurement. It is generally measured as the RSD of a set of repeated measurements. Accuracy is used to determine the difference between the evaluated measurement method and a measurement by a standard method. It is generally expressed as the RA. The size and excitation characteristics of a LIP can affect the amount of sample vaporized and the degree of excitation, and hence affect the LIBS accuracy and precision. Typical LIBS precision is 5–20%. Laser shot-to-shot variation causes differences in the plasma properties and therefore affects the magnitude of the element signal and hence degrades the LIBS precision. To improve LIBS precision, spectra from several laser shots have to be averaged in order to reduce statistical error due to laser shot-to-shot fluctuation.

The accuracy of LIBS depends on the sample composition, homogeneity, surface condition, and particle size generated. The sample matrix can affect the amount of element ablated and hence the LIBS signal. As LIBS only analyzes a small amount of sample, the result might be biased if the composition of the ablated sample does not represent the composition of the bulk. Multipoints measurements can improve the LIBS accuracy for an inhomogeneous sample.

For LIBS measurements based on the theoretical analysis of emission line intensity ratios, the accuracy depends greatly on the available spectroscopic constants, inferred temperature, and electron density. The uncertainty in these parameters is generally larger than 25%. Therefore, this is not a very accurate analysis method for LIBS. The best estimated accuracy with this technique is about 10%.

If the LIP condition is reproducible, calibration by emission line intensity is a more promising analysis tool for LIBS. The accuracy of this technique relies on absolute intensity measurement and therefore is affected by laser shot-to-shot fluctuation and particle size. Also this type of calibration shows a loss of sensitivity at high analyte concentrations due to self-absorption in the laser plume.

The sensitivity of AAS is dependent on the element, but is usually in the ppm region for flame AA and ppb region for graphite AA. Sample concentration techniques enable detection at even lower levels. Its precision is a function of several preparative, elemental, and instrumental conditions. Typically, the RSD associated with a flame absorption analysis is of the order of 1–2%. With caution, this figure can be lowered to a few 10ths of 1%.

The measurement precision of ICPAES is typically 1–5%. Thiem and Wolf have analyzed mining ores with both LIBS and ICPAES. They used certified reference soil as the test sample to determine Sr concentrations in soils. XFS measurements were obtained from a Spectrace™ 900 portable XFS unit with 200 s integration time and LIBS was performed with 10 s integration time (10 laser sparks). The certified soils have Sr concentrations in the range 26–380 ppm. The test results are shown in Table 3. Sr concentrations were measured from all the samples with LIBS except the sample containing 26 ppm Sr, which is below its detection limit. The LIBS precision was found to be in the range 3–18% and the XFS precision was between 3% and 23%. The RA obtained from these measurements were 0–44% for LIBS and 9–44% for XFS. The portable LIBS therefore has comparable accuracy and precision to a portable XFS unit. However, the portable LIBS has slightly poorer sensitivity for Sr than the portable XFS unit. This study indicates that LIBS has the same capability as an in situ screening device for soil as XFS.

* Sr signal was not detectable.

As a result of the small sample volume used the analytical capabilities of LIBS are generally poorer than most conventional methods. However, various studies have shown that LIBS is best for applications where standard laboratory instrumentation is not feasible, such as measurements in remote or harsh environments.

6 FUTURE DEVELOPMENTS

The development of LIBS has progressed rapidly since that late 1980s, with work on improving LIBS measurement of gas, liquid, and solid samples. The following research areas need to be strengthened before the technology reaches maturity for commercialization.

LIBS application as a CEM needs work on improving calibration methods, sensitivity and accuracy. An on-line calibration method needs to be developed for off-gas emission measurements. Sensitivity can be improved either by increasing the signal or reducing the background noise from the plasma and detector. Accuracy of the measurement can be improved by reducing pulse-to-pulse fluctuations of the laser-induced spark. Some toxic metals have analytical lines shorter than 200 nm, whereas optical fiber capability and detector sensitivity decrease considerably in this spectral region. Further work is therefore needed to improve measurement in this spectral region.

Further work is also required for the application of LIBS to the analysis of liquid samples. The main research areas of interest are studies of S/N for the laser spark produced with different liquid surfaces and bulk liquids, and techniques to measure concentrations at various depths. Quantitative measurement of solid samples with LIBS needs additional research to improve its analytical capabilities by improving the pulse-to-pulse spark reproducibility and laser ablation. Hybrid techniques such as combining LIBS with other discharge excitation sources need to be further tested to improve LIBS analytical capabilities. Matrix effects on concentration measurements also need further investigation.

LIBS has great potential for molten metal/glass applications. However, more detailed studies of LIBS on molten materials are needed.

To develop LIBS as a mature environmental analytical technique, work to commercialize a field LIBS instrumentation is also needed. Instrument size and cost should be reduced. A spectrometer that can measure simultaneously all the elements of interest needs to be developed.

Matrix Isolation Spectroscopy in Atmospheric Chemistry

K.S. Viswanathan, K. Sankaran, and K. Sundararajan
Indira Gandhi Centre for Atomic Research, Kalpakkam, India

There is a growing concern about our environment and it has been realized that quick and definite measures are required if we are to preserve our planet for posterity. The rising level of greenhouse gases in the atmosphere and its consequent effect on the global climatic conditions, the depletion of stratospheric ozone, acid rain, and photochemical smog are some of the issues that have been addressed by scientists and policy makers the world over. Solutions to most environmental problems can be obtained only through collective efforts and, to ensure that such efforts are effective, it is necessary that policies and legislation are made based on scientific data on our ever-changing environment. The data must provide information on the nature of trace constituents present in the different layers of the atmosphere, their concentrations, and their chemistry. A variety of experimental techniques have been used for this purpose, such as fluorescence spectroscopy, infrared (IR) and ultraviolet/visible (UV/VIS) absorption, Raman scattering, and photoacoustic spectroscopy. All these techniques exhibit some combination of the following features: multielement detection, low detection limits (DLs), specificity for an unequivocal identification of species, accuracy, and precision. One of the experimental techniques that has found important applications in the study of the atmosphere is matrix isolation (MI) spectroscopy. In this technique, the molecules of interest are diluted in a large excess of an inert gas and sprayed onto a cold substrate held at 10 K. Under these conditions, the molecules are trapped, isolated from each other and only surrounded by inert gas atoms. Such cold, isolated molecules yield spectra that have narrow spectral widths. Furthermore, if the trapped species are reactive molecules or radicals, they are likely to have extended lifetimes in the inert cage, thus allowing their chemistry and spectroscopy to be studied at leisure. These features of MI have made it particularly useful in the study of atmospheric chemistry. The high-resolution capability enables one to use this technique as an analytical tool, as closely lying spectral features of different molecules can now be resolved—a feature that has been employed to identify and estimate trace constituents in the upper tropospheric and stratospheric samples. In conjunction with gas chromatography (GC), MI and Fourier transform infrared (FTIR), referred to as GC/MI/FTIR, offers a powerful tool with which to resolve isomeric forms of environmentally hazardous chemicals such as polycyclic aromatic hydrocarbons (PAHs), dioxins, and polychlorinated biphenyls (PCBs). Such isomeric resolution is essential, as it is well known that only certain isomeric forms are biologically active, whereas the others are not. In this respect, GC/MI/FTIR even scores over GC mass spectroscopy (MS). Analytical spectroscopy of matrix-isolated species is also done using fluorescence spectroscopy, where again the advantage of high resolution enables one to resolve isomeric forms of compounds. Where the species of interest is a free radical, electron spin resonance (ESR) is the technique of choice to study the trapped species. This is a particularly powerful tool, as free radicals are known to play an important role in a number of atmospheric processes. Another aspect of MI spectroscopy is its ability to study reaction intermediates, a feature that has been employed to study the reaction mechanisms of atmospherically important chemical and photochemical reactions. All these aspects of the technique are discussed in this article, using examples.

1 INTRODUCTION

The remarkable technological growth that the human race has seen in recent decades is not without its influence on our environment. The increase in automobile exhaust emissions, effluents and emissions from industrial processes, and harmful and toxic effects of new chemicals have all contributed to changes in our atmosphere. There has been a growing concern over this deleterious effect of human “progress” and it has been realized for some time now that effective measures are imperative if we are
to preserve this planet for posterity. Implementation of the Montreal Protocol in 1987 and a subsequent London Revisions in 1990 restricting the use of chlorofluorocarbon (CFC) is an example of the legislative measures that have been sought. The United Nations First Conference on Environment and Development held at Rio de Janeiro in 1992, is also testimony to the concern shown by nations world over with regard to our environment. Although legislation is undoubtedly important, the formulation of effective legislative measures requires reliable data about our environment. Information is needed on the changes in the composition of the atmosphere over a period of time, and the effect of such changes on global climatic conditions.

Our environment is continuously altered by a variety of forcing agents, both natural and man made. For example, the concentrations of greenhouse gases such as carbon dioxide, methane, CFCs, and oxides of nitrogen have been on the rise. Some of these gases are also new additions, such as the CFCs, whose role in atmospheric chemistry is a twentieth-century phenomenon. Another activity that has an impact on our environment is biomass burning, which is resorted to for clearing forests for agricultural purposes and burning postharvest residues. In developing countries, the use of wood as a fuel material also serves to contribute to this process. As a result, the atmosphere is loaded with a variety of trace gases and particles, that have a profound influence on the atmosphere, both locally and globally. For example, the emission of oxides of nitrogen and sulfur, can result in acid rain, affecting the local ecology. However, species such as CO and CH₄ have global impacts. These species can significantly lower the concentration of OH radicals, which controls the concentrations of many atmospheric trace constituents and provides a sink for some of the greenhouse gases. A reduced concentration of the OH radicals may consequently increase the concentration of these greenhouse gases. It is therefore imperative to be alert to changes which is only possible by conducting a continuous “assay” of the atmosphere.

Before discussing the experimental techniques used to identify the atmospheric constituents, it may be worthwhile understanding a little about the structure of the atmosphere itself. The earth’s atmosphere is divided into many regions based on the temperature gradient, as shown in Figure 1. The region up to a height of about 10 km above the surface of the earth is the troposphere, the height that we usually touch during air travel. The region from 10 to 50 km is the stratosphere, where a number of important photochemical reactions take place. The impact that chemical species can have on our environment depends on where they are located in the atmosphere and their reactivity towards other species present alongside. For example, ozone in the troposphere contributes to undesirable greenhouse warming and has adverse effects on humans and vegetation, whereas its presence in the stratosphere is essential to filter ultraviolet (UV) radiation from the sun. It is therefore necessary to map the concentration profiles of the various species in the atmosphere. Such mapping is done by analyzing air samples collected over different regions on the land and sea and at different heights in the atmosphere. Furthermore, the lifetimes of these species in the atmosphere is determined by their chemical reactivity and their transport dynamics. For a clear understanding of the ever-evolving atmosphere, it is necessary to understand its composition with respect to the major and trace constituents, their chemistry, and transport phenomena.

The experimental techniques used for the study of the atmosphere can be classified into two groups. The first of these are analytical methods to identify and estimate atmospheric constituents. A number of spectroscopic techniques are used for this purpose, such as fluorescence spectroscopy, IR and UV absorption, differential optical absorption spectroscopy (DOAS), photoacoustic spectroscopy, and laser-based methods involving both photon and ion detection. These techniques exhibit all
or some combination of the following features: low DLs, specificity for an unequivocal identification of species, multispecies detection, accuracy, and precision. The second category of studies are aimed at understanding the kinetics and mechanisms of reactions and reaction intermediates, which play an important role in the photochemical processes of the atmosphere. These studies are generally conducted using laser-based pump-probe methods, IR and UV absorption, and ESR spectroscopy. The first category of experiments provide information on what species are present in the atmosphere, whereas the second describes their reactivity.

This article discusses the use of MI spectroscopy for atmospheric studies, both as an analytical tool and to study reaction mechanisms and intermediates, relevant to atmospheric processes. MI is a technique in which the molecules of interest are isolated in a cold, inert gas matrix and studied using a variety of spectroscopic techniques such as IR, fluorescence, ESR, and Mossbauer spectroscopy, to name a few. The technique has been widely used to study conformations, hydrogen bonded and van der Waals molecules, and high-temperature species; its use in atmospheric studies is yet another example of its utility.

2 NEED FOR A TECHNIQUE SUCH AS MATRIX ISOLATION

To appreciate the need for the technique of MI, it is worthwhile taking a look at spectra obtained with the commonly employed gas-phase and condensed-phase sampling methods. To build up this discussion, the IR spectra of a few compounds are considered.

Figure 2 shows the IR spectra of ethylene, benzene, and benzoic acid, serving as typical examples of gas, liquid, and solid samples, respectively. Ethylene at a pressure of 1 torr was used to fill a 6 in path-length gas cell, benzene was taken as a liquid film on a zinc selenide substrate, and benzoic acid was impregnated in a KBr pellet (0.5%). All these sampling methods are popularly used in IR spectroscopy. The peaks seen in the spectra reflect absorptions corresponding to vibrations of specific groups of atoms in the molecule.

What should be noted in these spectra are the widths of the spectral features. The absorption peaks in Figure 2 display a width that is typically about 20–30 cm\(^{-1}\). In the case of gas-phase samples, the spectra consist of a large number of sharp lines with the contour extending to almost 100 cm\(^{-1}\). Very often large spectral widths or contours are undesirable, particularly in experiments where it is required to identify the constituents in a multicomponent mixture. Two closely lying spectral features of two different compounds can be unambiguously resolved only if the peak width is small compared with the separation between the peaks. It is therefore necessary to be able to obtain spectra with small peak widths.

2.1 Broadening Mechanisms

To reduce the width of the spectral features, it is necessary to understand what broadens them in the first place. There are a number of reasons as to why spectral features are broadened,\(^3\) including

- natural broadening;
- Doppler broadening;
- collisional broadening;
- distribution of molecules over a number of energy states;
- interactions between molecules.

2.1.1 Natural Broadening

This arises owing to the finite lifetimes of excited states and is a manifestation of the Heisenberg uncertainty principle. The shorter the lifetime of a state, the greater is the uncertainty in the energy of that state. Consequently, the spectral width of a transition associated with that state will be large. The experimentalist has hardly any control over this broadening mechanism.

2.1.2 Doppler Broadening

Doppler broadening is a consequence of molecular motion in a sample. The relative motion of the molecules and the source (or detector), causes the transition frequency to be shifted; the magnitude and direction of
the shift depend on the relative velocity of the molecule with respect to the source (or detector). (Recall the varying pitch of a hooting locomotive as it approaches and then recedes from you.) As the molecules in a sample have a distribution of molecular speeds given by Maxwell's distribution, the transition frequencies are also distributed over a range of values, leading to a broadened spectral profile. The higher the temperature, the greater is the width of the speed distribution and hence the larger the peak width due to Doppler broadening.

2.1.3 Collisions
The collisions that occur between molecules, both elastic and inelastic, are also responsible for broadened spectral features. Inelastic collisions tend to shorten the lifetimes of the excited states, which culminates in a broadened profile. However, elastic collisions may result in phase perturbations during absorption or emission which can result in peak broadening.

2.1.4 Energy States
The distribution of molecules over various energy states, corresponding to rotational and vibrational motion, is also a cause of broad spectral profiles. For example, the large number of sharp peaks seen in the gas-phase spectrum of Figure 2 (trace A), corresponds to transitions from a number of rotational levels of ethylene; such complexities in spectra are referred to as spectral congestion.

2.1.5 Intermolecular Interactions
These can also perturb energy levels, leading to spectral broadening.

Only some of the broadening mechanisms have been discussed here; there are others, such as pressure broadening, time-of-flight broadening, etc. A detailed treatment of these can be found in textbooks on spectroscopy. All or some combination of these factors play a role in broadening the spectral features of a sample.

A number of these broadening mechanisms depend on the temperature of the sample. For example, if the temperature $T$ of the sample is lowered, the width of the speed distribution decreases. As a result the Doppler width, which can be shown to be proportional to $\sqrt{T}$, also decreases. Lowering the temperature also restricts the population to only a few rotational and vibrational levels, which gives rise to spectra with fewer features. It may therefore appear that by simply lowering the temperature of the sample, one can obtain a reduction in the peak widths. However, this is not necessarily the case, as Figure 3 shows. The IR spectra of liquid trimethyl phosphate at room temperature is compared with the frozen compound at 12 K. In spite of the decrease expected in the Doppler width and spectral congestion at low temperatures, almost no reduction in peak width is obtained. This is because intermolecular interactions continue to operate in the frozen sample, resulting in broad spectral features.

It is therefore necessary not only to cool the samples, but also to minimize the intermolecular interactions, by isolating the molecules from each other.

The common sampling methods mentioned earlier – gas, liquid, or solid – cannot combine low temperatures and isolated-molecule conditions. It is therefore necessary to look beyond the common sampling methods to produce cold and isolated molecules. MI spectroscopy is one such experimental technique.

Although the above discussion uses IR spectroscopy as an example, the arguments apply equally well to other branches of spectroscopy.

3 MATRIX ISOLATION SPECTROSCOPY
In an MI experiment, vapors of the sample of interest are mixed with a large excess of an inert gas, such as argon.
or nitrogen, and this gas mixture is then sprayed onto a cold substrate (≈10 K). The inert gas to sample ratios are typically 1000:1. The large excess of an inert gas ensures that when the gas mixture freezes on the substrate, the sample molecules are mostly trapped isolated from each other and only surrounded by inert gas atoms, as depicted in the cartoon (Figure 4a). To a first approximation it can be assumed that the inert gas atoms do not interact with the trapped species, which therefore reside in an inert cage. This environment is devoid of strong intermolecular interactions, as opposed to the situation for a liquid sample (Figure 4b). The low temperatures of the matrix also ensure that only the low vibrational and rotational levels are populated. Furthermore, the low temperatures and the rigid matrix cage constrain molecular motions and lead to an elimination of the Doppler width. Figure 5 shows the IR spectra of gas phase acetylene, and acetylene trapped in an argon matrix at about 12 K. The extensive rotational contour that extends over 100 cm\(^{-1}\) in the gas phase is absent in the matrix-isolated spectra, which displays a sharp peak with a width of only about 2 cm\(^{-1}\). Cooling and isolating the molecules in an inert environment has therefore done the trick!

Apart from sharp spectral features, another important feature of the MI technique is the interaction-free environment that it provides for the trapped species. If the trapped species are reactive, such species now have extended lifetimes, simply for want of a reaction partner. Without the isolation, the reactive species would most likely annihilate themselves by reacting with each other or with the surrounding species. Spectroscopic studies of reactive species trapped in an inert matrix can therefore be made at leisure; a feature which makes it possible to study intermediates in chemical reactions. Historically, MI was first developed for this very purpose of studying transient species, by trapping them in inert matrices.\(^4\) MI therefore presents a twofold advantage. First, it can be used as an analytical tool for the estimation of the constituents in an atmospheric sample. In these applications the small line widths afforded by the technique is taken advantage of. Figure 6 illustrates this aspect of MI spectroscopy, where the gas-phase and matrix isolation infrared (MI/IR) spectra of a five-component mixture consisting of ethylene and deuterated ethylene are presented.\(^5\) It is clear that the peaks due to the different components in the mixture are clearly resolved in the MI spectra. Furthermore, the small peak widths also lead to larger peak heights, thereby rendering measurements of peak intensities more accurate. Consequently, low concentrations can be accurately measured in MI experiments. Second, the ability of the technique to trap reactive species can be used to study the structure and reactions of species involved in atmospheric chemical processes. Both aspects are highlighted in the discussions that follow.

**Figure 5** Comparison of IR spectra of acetylene: (A) in the gas phase, (B) trapped in an argon matrix at 12 K.
MI is fundamentally a sample preparation technique. Once the species are trapped in the inert matrix, a variety of spectroscopic methods may be used, such as IR, UV/VIS, and ESR spectroscopy. The studies performed on the trapped species depends on the information being sought.

3.1 Experimental Aspects

A detailed treatment of the experimental aspects of MI is given in many text books on this subject. Only a broad outline, detailing the important aspects of the technique is presented here. The MI equipment consists of:

- a cryostat to produce the low temperatures;
- a vacuum system to house the cold tip, where the sample is deposited;
- a sample handling system and deposition lines;
- a spectrometer to record the spectra of matrix-isolated species.

3.1.1 Cryostat

A cryostat is used to produce the low temperatures required to deposit the sample and the inert gas. Cryostats are of three types.

3.1.1.1 Liquid Refrigerant-based Cryostats

In these cryostats, liquid refrigerants such as helium (4.2 K), liquid nitrogen (77 K) and liquid air (90 K) are used to attain low temperatures. The earliest designs involved a tubular reservoir, in which the liquid refrigerant is filled. To this reservoir is attached a sample window on which the matrix is deposited. Where liquid helium is used, a double-Dewar arrangement is essential to minimize the evaporation loss of the expensive refrigerant. In this design, the liquid helium reservoir is surrounded by a reservoir of liquid nitrogen, the secondary refrigerant acting as a heat shield.

In later modifications, liquid helium was passed through the reservoir to which the cold finger is attached. These continuous-flow cryostats do not require a secondary...
refrigerant. They are also more economical than double-Dewar cryostats, and are compact and portable.

3.1.1.2 Joule–Thomson Open Cycle Cryostat In this type of cryostat a high-pressure gas is expanded through an orifice to produce low temperatures. This design does away with the need to handle liquid refrigerants and are extremely compact. Commercial models are available that cover the temperature range 4–200 K.

3.1.1.3 Closed Cycle Cryostats This type of cryostat is the most popular. In these cryostats, which work on the principle of the Gifford–McMahon cycle, cooling is achieved by the continuous compression and expansion of He, in an enclosed space. Helium is first compressed to a pressure of about 20 bar and the heat of compression is removed by circulating cold water. The helium is then delivered to the cold head, where it expands against a piston, and eventually cools the regenerator. The expanded helium is then returned to the compressor for the next cycle. Although the initial capital costs of these cryostats are high, they involve almost no running costs and are extremely easy to handle.

3.1.2 Vacuum System

The cryotip onto which the sample is deposited is housed in a vacuum system. A vacuum system is necessary to maintain the low temperature and also to provide a clean environment in which the matrix can be deposited. A vacuum of better than 10⁻⁶ mbar is essential for the successful conduct of an MI experiment. The presence of impurities, apart from producing impurity peaks, can also lead to complications by forming complexes with the molecules of interest. Hence the need to maintain a high vacuum in these experiments cannot be overemphasized. A diffusion pump backed by a rotary pump is popularly used to produce the necessary high vacuum. Although diffusion pumps are easy to handle and relatively inexpensive, problems due to oil backstreaming into the vacuum chamber can at times be annoying. This problem can be surmounted by using a liquid-nitrogen trap. However, wherever possible, it may be desirable to use oil-free high-vacuum pumps, such as a turbomolecular pump.

3.1.3 Deposition of the Matrix

A variety of deposition schemes is used to prepare the matrix-isolated sample. In the simplest case, the matrix gas and the sample(s) of interest are mixed to the desired concentrations in a mixing chamber using manometric procedures and this gas mixture is then sprayed onto a cold substrate through a nozzle. The flow through this nozzle, which is generally effusive, is controlled using fine flow-control valves. Typical deposition rates are about 1 mmol h⁻¹ of matrix gas. Deposition rates should be controlled to ensure good optical quality of the matrices and also to prevent any excessive heat liberation during matrix condensation. Undue temperature rise of the cold finger can cause diffusion of the solute molecules, leading to undesirable aggregation. As a variation of the above deposition procedure, the matrix and the sample can be taken in two different containers and passed through two different nozzles, referred to as a twin-nozzle system. In this set-up, mixing of the matrix gas with the sample occurs soon after effusion out of the nozzle and the mixture then deposits on to the cold tip. In such experiments, the required matrix to sample ratio is achieved by controlling the relative flow rates of the sample and the matrix gas. As a logical extension, where reactions between two precursors are to be studied, a triple-jet assembly is used, where the matrix gas and the two samples effuse out through three separate nozzles. The different nozzle designs are shown in Figure 7.

The methods of sample deposition described above are employed where stable molecules are to be studied. For the study of reactive species, variations of the above procedures are employed. A stable species can be first deposited, followed by photolysis to yield the reactive species. For example, photolysis of W(CO)₆ in an Ar matrix yielded the reactive W(CO)₅ and CO. Alternatively, the reactive species can be produced in the gas phase (prior to deposition) by passing the sample(s) through an electric discharge or by subjecting it to photolysis, and the reaction products are then

![Figure 7](image-url)
trapped in the inert matrix. For example, XeCl$_2$ can be prepared by passing Xe and Cl$_2$ through a discharge tube. As mentioned earlier, these reactive species, which normally would have instantaneously indulged in a chemical reaction destroying themselves, now have extended lifetimes in the inert cage. This technique has been exploited for studies on atmospheric chemistry, as reactive molecules expected to participate in atmospheric processes can be trapped in the matrix for spectroscopic analysis and study of their reactions.

3.1.3.1 Annealing  Once the sample and matrix are deposited, a spectrum of the matrix-isolated sample is recorded. Very often, a spectrum of the sample is also recorded after annealing the matrix. Annealing is a process where the temperature of the matrix is raised to about 0.4 $T_m$, where $T_m$ is the melting point of the matrix material. The matrix is held at this temperature for some time, (typically about 15 min to 1 h) and then recooled to 12 K. Annealing of the matrix is done for two reasons. First, it removes unstable sites in the matrix in which the sample molecules may be trapped. The sites referred to are the different environments in which the sample molecules are trapped in the lattice formed by the inert gas during deposition. One such environment is formed by substituting the sample molecules for one or more of the matrix atoms; such a site is referred to as a substitutional site and is the most likely one for large molecules. Alternatively, the sample molecules may occupy either a dislocation or an interstitial site. The interstitial site is usually too small to accommodate most molecules other than small diatomics. Dislocation sites are large but nonuniform. Although some of these sites may be unstable, they may nevertheless be formed during matrix deposition owing to the rapid freezing. The presence of these different sites may be signaled by the appearance of multiplets in a spectra. Annealing the matrix generally simplifies such spectra, by removing sites that are unstable. Figure 8 shows the spectra of trimethyl phosphate recorded after deposition and after annealing the matrix. It can be seen that with the loss of the unstable sites, the spectral features sharpen on annealing. As discussed below, the role of sites in MI spectra is particularly relevant in the study of fluorescence of species trapped in hydrocarbon matrices. Another reason to anneal the matrix is to deliberately cause diffusion of the solute molecules in an effort to drive a reaction. The diffusion may cause two molecules, (which were initially isolated) to approach each other and form aggregates. Appearance of new peaks following annealing is generally a signature of the occurrence of such reactions.

3.1.3.2 Matrix  Substances must possess certain properties for them to serve as matrices. They must be inert so that they do not perturb or react with the trapped species. At the temperatures of the MI experiments, the substance must form a rigid matrix, so that the molecules of interest may be held isolated. If this criterion is not met, the trapped species will diffuse, leading to undesirable reactions. At the same time, the substance must be volatile at room temperature, so that it may be conveniently deposited onto the cold substrate. It is also important that the matrix substance must be available with a high degree of purity and not have any spectral absorptions in the region of interest.

Inert gases and nitrogen generally meet the above criteria and are used as matrix gases. Among the inert gases, argon and to a lesser extent neon and xenon are commonly used. These gases are popular where IR spectroscopy is used to probe the trapped species, as these matrix materials do not have any IR absorptions. There have been specific instances where other materials, such as carbon dioxide, water (or D$_2$O), and hydrocarbons, have been used as matrices. These are discussed later.
3.1.4 Spectrometer

Once the sample molecules are isolated in the matrix, they are studied by using any of the spectroscopic methods, such as IR, fluorescence, or ESR spectroscopy. The choice of the spectroscopic technique is generally determined by the type of information one is looking for. For example, an analytical exercise is usually undertaken using IR and fluorescence spectroscopy, whereas studies on free radicals (which may be reactive intermediates in a photochemical reaction), are usually performed using ESR and IR spectroscopy.

A MI set-up is shown in Figure 9. Details of the experimental and theoretical aspects of the technique can be found in a number of treatments on this subject.

4 APPLICATIONS

4.1 Analytical Spectroscopy

MI has been used as an analytical tool for the detection and quantitative estimations of trace constituents in the atmosphere. As mentioned earlier, this application stems from the fact that the spectral features in MI experiments have small line widths, which makes it possible to resolve closely lying peaks of the different constituents.

Analysis of air samples can be classified into two groups: first, those that monitor the occurrence and concentrations of species that have a long-term effect on the climatic conditions of the earth; second, those that serve to identify the presence of hazardous chemicals that pose a threat to the local environment. Examples of the first class are the study of air samples from the upper troposphere and stratosphere for species such as OH radicals, oxides of nitrogen, sulfur, and halogens, carbonyl halides, halomethanes, and peroxides. It is now realized that these species play an important role in the earth’s atmospheric chemistry, and data on such species serve as inputs for atmospheric modeling exercises. Examples of the second class are the study of air samples to monitor the presence of toxic substances such as PAHs and PCBs. In these analyses the air samples are collected from nearer to the earth’s surface.

The use of MI spectroscopy for these analytical studies in conjunction with IR, fluorescence, and ESR spectroscopy is now reviewed.

4.1.1 Matrix Isolation Infrared Spectroscopy

First, the use of this technique for studies on upper tropospheric and stratospheric samples is considered, together with problems associated with such studies. Studies on near-ground-level samples are then discussed.
4.1.1.1 Samples from the Upper Troposphere and Stratosphere

A number of species that dominate the chemistry in these regions of the atmosphere are labile; it can therefore be extremely difficult to retain the identity of these species until they are brought back to the laboratory for MI studies. Sample collection techniques that retained the identity of the species had therefore to be worked out. In one of the first attempts, a closed cycle refrigerator was transported in a military aircraft to collect air samples at altitudes of around 15 km. The cryostat was then brought back to the laboratory for analysis. Although these first attempts by Snelson\(^\text{12,13}\) did not particularly succeed in obtaining MI data, they nevertheless paved the way for future studies.

The work of Griffith has contributed significantly towards the development of reliable sample collection methods and pretreatment.\(^\text{14}\) Associated with the problem of sample collection, the choice of a suitable matrix material is also an important question to be addressed, which is discussed first.

**Choice of the Matrix Material.** It was recognized that instead of the commonly employed matrix gases, such as Ar or N\(_2\), there was a significant advantage to be derived by using the CO\(_2\) present in the air sample itself as the matrix gas.\(^\text{14}\) Carbon dioxide is present in air to the extent of 350 ppmv. Other trace gases are present in the air sample, at concentrations about 1000 times lower. For example, N\(_2\)O is present at levels around 300 ppbv. If the CO\(_2\) present in the air is used as the matrix, the sample to matrix ratio, (such as N\(_2\)O/CO\(_2\)) would be about 1 : 1000, which is typical in MI experiments. If argon had been used as the matrix, as is usually done in MI experiments and the air to argon ratio were 1 : 1000, then the CO\(_2\) to argon ratio would be about 3 : 10\(^6\), and the N\(_2\)O to argon ratio would be about 1.3 : 10\(^6\). These concentrations are extremely low. The choice of CO\(_2\) as the matrix, can therefore be seen to preconcentrate the trace constituents, and is the key to the success of the experiment. The use of CO\(_2\) as the matrix poses problems of interfering IR absorption bands, as CO\(_2\) has strong IR absorptions. However, useful spectral windows are still available with this matrix for use in trace gas analysis. Interestingly, these interfering CO\(_2\) bands have been used to advantage to monitor the thickness of a CO\(_2\) matrix, as discussed later.

**Method of Air Sample Collection and Pretreatment.** Having decided on the matrix, the next question to be addressed is the method to be adopted to collect the atmospheric samples. It is necessary to be able to collect the air sample and transfer it to the cold finger along with the matrix gas, CO\(_2\), with little loss of sample integrity. Obviously, the best method would be to deposit the air sample directly on to a cold substrate without any sample treatment. If the substrate temperature is maintained at 77 K, only CO\(_2\) (to be used as the matrix) and other nonvolatile constituents would deposit. This procedure was not often successful, particularly for IR studies, because the water normally present in the air samples to the extent of about 1 ppmv led to poor-quality matrices. Furthermore, the condensation of CO\(_2\) in the presence of large quantities of N\(_2\) and O\(_2\), the major constituents of air, also resulted in poor-quality matrices. Hence some amount of sample preparation was necessary before the air sample could be analyzed.

After considerable research effort, a two-step process was devised, to prepare dry air samples.\(^\text{14}\) The field samples were drawn into a cryosampler, and maintained at liquid nitrogen temperatures. In the laboratory, the sample was evaporated by raising the temperature of the cryosampler carefully to a predetermined value. This temperature of evaporation was determined by the amount of water expected to be present in the field sample. Where the water content was low, such as in upper tropospheric samples, the temperature of evaporation was maintained at about –50 °C. However, where the water content was expected to be high, such as in air samples collected nearer to the earth’s surface, lower evaporation temperatures were employed or drying agents such as P\(_2\)O\(_5\) were used.

Care must be exercised during such drying procedures as chemical modifications of the sample species may occur, which is obviously undesirable.

**Quantification Procedure.** Once the matrix-isolated sample is prepared, quantification of the trace species is done using the celebrated Beer–Lambert law, although the application of the law in this case needs a little elaboration. The Beer–Lambert law can be written in the form (Equation 1)

\[
A = \varepsilon \times c \times d
\]

where \(A\) is the integrated absorbance of the analyte, \(\varepsilon\) is the integrated absorption coefficient expressed in appropriate units, \(c\) is the concentration of the analyte in the sample (which in this case is the concentration of the analyte in the CO\(_2\) matrix), and \(d\) is the matrix thickness. In the usual application of the Beer–Lambert law, \(d\) represents the path length of the cell containing the sample. This quantity is generally known a priori, or at least remains a constant and can therefore be absorbed into a calibration plot. In the MI experiments, the matrix thickness \(d\) is a variable, depending on the rate and duration of deposition, and must therefore be measured for each experiment. The matrix thickness is usually measured using interference techniques with an He–Ne laser. Griffith and group devised a method that used the intensity of CO\(_2\) (matrix) absorption line as a thickness monitor. A series of measurements was made of the
intensities of the different CO₂ absorption lines, together with a direct thickness measurement using the He–Ne interference method. This data enabled the absorption coefficient of the different lines in the CO₂ IR spectrum to be evaluated. Using this data, the thickness d of the CO₂ matrix can be calculated, simply by monitoring the integrated absorbance of any of the CO₂ peaks. A detailed discussion of this method is given by Griffith.\(^{(14)}\)

For the estimation of the trace gas concentrations, calibration plots are obtained by taking known concentrations of the trace gas in question, in a CO₂ matrix and measuring the intensities of its absorption line. From the calibration plot, one evaluates the concentration of the trace gas with respect to CO₂ in the atmospheric sample. If the mixing ratio of CO₂ in air is known, the concentration of the trace gas in air can be estimated. The mixing ratio of CO₂ in air can be separately determined by taking the air sample in a gas cell for gas-phase spectral analysis. It must be remembered that the straightforward gas-phase method cannot be applied to trace gas estimation, because the low concentration precludes such a simplistic determination.

Figure 10 provides an example of the analysis of an air sample collected from the upper troposphere from a Lear Jet.\(^{(15)}\) Species such as COCl₂, OCS, and freons were identified in this sample, in addition to other carbonyl halides such as COFCl and COF₂. These species were found to be present at mixing ratios of approximately 20 pptv in the upper troposphere and increased with height in the lower stratosphere. The identification of the carbonyl halides in the upper tropospheric samples raised the question as to where they were formed. It is now believed that the carbonyl halides are formed by the oxidation of chlorinated hydrocarbons in the troposphere, and then transported to the stratosphere. (A later section describes how the oxidation of halocarbons was studied using MI spectroscopy.) Once in the stratosphere, carbonyl halides dissociate photolytically to yield free chlorine, which plays an active role in ozone depletion. The point that this study drives home is that an oxidative species from the troposphere may have an impact on stratospheric ozone depletion – a useful input for ozone-depletion models. The same study\(^{(15)}\) also pointed out that phosgene mixing ratios of 17 pptv in the upper troposphere and 22 pptv in the lower stratosphere were greater than those estimated by models which assumed CCl₄ as the only source. These experiments therefore implied that other sources of phosgene must be present, such as CHCl₃, CH₂CCl₃, C₂HCl₃, and C₂Cl₄. This study is a classic example of how detection and quantification of trace species in the atmosphere can serve as useful inputs for atmospheric models.

4.1.1.2 Samples from Near to the Earth’s Surface  In the second class of analysis of air samples, the problem is to identify and measure the concentrations of hazardous chemicals, such as PAHs, chlorinated dioxin and dibenzofuran derivatives, and PCBs, that pose a threat to the local environment. In these applications involving usually stable species, GC is used in conjunction with MI spectroscopy. The sample mixture is first subjected to a gas chromatographic separation and the material that is eluted is deposited on a rotating gold-plated cryogenic surface. The samples eluting at different times are deposited on different points on the cryogenic surface. In these experiments, helium–argon mixtures are used as the carrier gas for chromatography. The argon present in this mixture serves as the matrix gas to prepare the matrix-isolated sample. The deposited chromatogram is stored on the cryogenic surface and an IR spectrum then recorded. The technique is referred to as GC/MI/FTIR, where the matrix isolation/Fourier transform infrared (MI/FTIR) detection scheme replaces the light pipe probe used in conventional GC/FTIR. The GC/MI/FTIR method is more sensitive and has a higher spectral resolution than conventional GC/FTIR. Figure 11 compares a spectrum of N-nitrosodimethyl amine recorded using GC/MI/FTIR with that recorded using a light-pipe-based absorption.\(^{(16)}\) The MI/FTIR detection clearly offers spectra with better signal-to-noise ratio (S/N) than the light-pipe detection. The superior S/N in the MI/FTIR spectra is due to the signal-averaging capabilities offered by this technique. Furthermore, light pipes are usually heated to prevent...
condensation of the eluted samples. The heating gives rise to an IR background in the light-pipe detection.

The single most attractive feature of GC/MI/FTIR is its ability to distinguish between isomers. This advantage is of paramount importance, as it has been shown that biological toxicity is often highly isomer specific. For example, amongst the polychlorodibenzo-p-dioxins, the 2,3,7,8-tetrachloro isomer is the most toxic. Similarly, benzo[a]pyrene (B[a]P) is a potent carcinogen, whereas its isomer benzo[e]pyrene is significantly less hazardous. From the point of view of environmental monitoring and waste management, it is therefore essential that the analytical technique possess the ability to resolve isomers. Figure 12 (trace A) shows the GC/MI/FTIR spectrum of a fraction that eluted out of the GC column at a certain time (31.58 min). This spectrum did not find a match in the MI/IR spectral library, and it was suspected that the eluted fraction may contain a mixture of an isomer pair. It is clear from traces B and C, which are reference spectra of chrysene and triphenylene, that the eluted fraction contained both these isomers. The example clearly demonstrates that compounds eluting simultaneously can still be differentiated using MI/FTIR. In this regard, GC/MI/FTIR even scores over mass spectroscopic detection, which enjoys superior DLs, but is not always capable of resolving isomeric species. For example, electron impact ionization mass spectra of chrysene and triphenylene yielded identical parent ions, similar fragmentation patterns and only subtle differences between the two spectra, making differentiation between the two isomers difficult. Similar resolving capabilities were also demonstrated for the B[a]P/benzo[e]pyrene pair, and benzofluoranthene isomers.

4.1.2 Matrix Isolation Fluorescence Spectroscopy

Fluorescence spectroscopy has been extensively used as an analytical tool for condensed- and gas-phase samples. Compared with absorption spectroscopy, fluorescence spectroscopy has superior DLs, which has made it the technique of choice for trace level estimations.

Obtaining sharp absorption and emission lines is again a principal motivation for doing fluorescence spectroscopy of matrix-isolated samples. However, unlike in IR spectroscopy, where inert gases and nitrogen are excellent matrices, the choice of the matrix is not so straightforward in fluorescence. The same considerations as those discussed earlier for sharpening of spectral lines apply here too, except that the site effects are extremely important...
in this case. Molecules trapped in different environments can display a multitude of spectral features. If a matrix can be chosen in which the molecules can be trapped in a few well-defined sites, spectral simplification may occur, leading to sharp spectral features, referred to as the Shpol’skii effect.\(^{(19)}\) Hydrocarbons, such as hexane and octane, have often proved to be successful Shpol’skii matrices. It has been realized that the best matrices are those in which one of the dimensions of the solute molecules is similar to the length of the hydrocarbon chain. In such systems, the solute preferentially occupies a well-defined site, leading to line narrowing. Figure 13 shows the laser-induced fluorescence spectra of the environmentally important B[\(a\)]P trapped in heptane and octane matrices.\(^{(20)}\) It can be seen that the spectrum in the octane matrix is sharper than that in the heptane matrix, which displays a multiplet structure. The sharp spectral feature in the octane matrix may be useful in characterizing the trapped species for analytical applications.

Furthermore, the trapped species exhibit sharp features in absorption too, which allows one to selectively excite a particular species in a well-defined site, using a narrowband excitation source, such as a dye laser. This aspect was convincingly presented by D’Silva and Fassel.\(^{(21)}\) They showed that each component in a multicomponent mixture can be selectively excited to obtain a fluorescence spectrum corresponding to each of the trapped species. Figure 14 shows the spectra of four different PAHs, obtained by a selective excitation of each of the species in the mixture, using dye laser excitation. The sample was a solvent-refined coal liquid sample trapped in an \(n\)-octane matrix. Occasionally, a partial overlap of the absorption lines may lead to spectra of more than one compound being observed. For example, at the excitation wavelength (380.14 nm) where B[\(a\)]P was excited, the feature for B[\(k\)]F was observed; likewise the B[\(k\)]F fluorescence spectra, excited at 378.94 nm showed features of B[\(a\)]P. However, as can be seen from the spectra, the emission lines are sufficiently sharp to allow for identification of the different components in the mixture. Similarly, all the components in a mixture consisting of six mono-, two di- and three tri-alkylated benz[\(a\)]anthracenes were shown to be unequivocally identified.\(^{(21)}\) The technique can therefore be seen to yield isomer-specific detection of samples, essential in the characterization of hazardous wastes.

However, a notable disadvantage of the Shpol’skii experiment is that the choice of matrix is not always obvious. A given compound or a class of compounds may have only a few matrices where the Shpol’skii effect may be observed. Secondly, some compounds may photodecompose in a Shpol’skii matrix. However, wherever applicable, MI fluorescence spectroscopy, utilizing laser-excited site selection (LESS), has been extremely useful in toxic waste evaluation, prompting the remark that one can “Do more with LESS.”\(^{(21)}\)

### 4.1.3 Matrix Isolation/Electron Spin Resonance Spectroscopy

As free radicals play an important role in atmospheric processes, it can only be expected that ESR spectroscopy would be a useful tool for these studies. The reactive
free radicals can be trapped in the inert matrix and then studied using ESR.

The matrix is deposited on sapphire or copper block substrates and the cold finger then introduced into the microwave cavity for ESR measurements. The unstable radical species survive in the inert matrix, on which ESR studies are performed. Details of the matrix isolation/electron spin resonance (MI/ESR) set-up and experimental procedures can be found in treatments on this subject.\(^{14,22}\) In experiments where MI/ESR is used for atmospheric studies, CO\(_2\) again turns out to be a useful matrix. Water (or D\(_2\)O), which are avoided in IR experiments, serve as a useful matrix for ESR studies. Oxygen, being paramagnetic, must be avoided in the matrix, or else it can interact with the deposited free radicals causing significant line broadening, something which the MI technique set out to eliminate in the first place! The first attempts of Snelson\(^{12}\) did not yield useful spectra, essentially because the sampling method adopted then, which was to simply freeze out the air sample on to the matrix substrate, incorporated O\(_2\) in the matrix.

Mihelcic et al. obtained MI/ESR spectra of free radicals by trapping them in CO\(_2\) and H\(_2\)O matrices.\(^{23,24}\) Oxygen was eliminated by maintaining the cold finger at liquid-nitrogen temperatures. In these experiments, care was taken to minimize the collisions of the sampled radicals with any of the surfaces of the sample compartment other than, of course, the cold finger. This was achieved by having the sampled air form a gas jet that concentrates around the cold finger. In early experiments,\(^{23}\) the CO\(_2\) and H\(_2\)O present in the sampled air were used as the matrix. However, it was soon realized that the trapping efficiency was low in such experiments and depended on the H\(_2\)O concentration, which was variable in the troposphere. They ensured a stable and a large collection efficiency by deliberately adding water during the matrix deposition. In later experiments, they showed that the use of D\(_2\)O yielded ESR spectra with smaller linewidths than those obtained with an H\(_2\)O matrix.\(^{24}\)

Figure 15 shows the ESR spectra of free radicals, NO\(_2\), NO\(_3\), HO\(_2\), and CH\(_3\)COO\(_2\), trapped in H\(_2\)O and D\(_2\)O matrices.\(^{24}\) The spectra in the D\(_2\)O matrices are

![Figure 15 MI/ESR spectrum of common atmospheric radicals trapped in H\(_2\)O (upper trace) and D\(_2\)O (lower trace) matrices at 77 K: (a) NO\(_2\), (b) NO\(_3\), (c) HO\(_2\), (d) CH\(_3\)COO\(_2\). (D. Mihelcic, A. Volz-Thomas, H.W. Patz, D. Kley, M. Mihelcic, ‘Numerical Analysis of Electron Spin Resonance Spectra from Atmospheric Samples’, Journal of Atmospheric Chemistry, 11, 275 (1990), Figure 1, with kind permission from Kluwer Academic Publishers.)](image-url)
clearly sharper, resulting in greater sensitivity, and also allow for the identification of those radicals that show a characteristic hyperfine structure.

Using the experimental procedures described above, Mihelcic et al. studied the diurnal variation of NO2 and RO2 (total peroxy concentration). Their studies showed that the concentrations of NO2 and RO2 were anticorrelated and that the nighttime RO2 concentration hardly differed from those obtained during the day. In another experiment, they also measured the vertical concentration profiles of NO2 and RO2 over altitudes ranging from 1 to 6 km. Using a least-squares spectral analysis algorithm, they showed that small amounts of HO2 could be detected in the presence of a manyfold excess of NO2 and other peroxy radicals. HO2 and CH3COO2 radicals in tropospheric samples were shown to be detected at concentrations up to 40 pptv.

Being reactive species, free radicals play a very important role in the chemistry of the atmosphere and the MI/ESR technique provides a powerful technique with which to study them.

### 4.2 Study of Reaction Intermediates

To understand the chemistry and the various dynamic processes in the atmosphere, it is important not only to identify and quantify the different species present, but also to elucidate the important chemical reactions that they manifest. Many atmospheric reactions are photochemically driven processes involving reactive species. MI is a technique ideally suited for the study of such process as the following examples will show. The examples cited here are only representative and are not an exhaustive compilation.

As an example of the use of MI for the study of reactive species, some of the work pertaining to stratospheric ozone depletion is described. In this context, it is relevant to briefly review some of the chemistry involving ozone depletion. Many atmospheric reactions are photochemically driven processes involving reactive species. MI is a technique ideally suited for the study of such processes. MI/IR spectroscopy, where they studied the reaction between ClO and NO2 by photolyzing flowing mixtures of Cl2, Cl2O, and NO2 and trapping the reaction product in an

Equation (5) regenerates atomic chlorine and the cycle is resumed. (The atomic oxygen, involved in Equation (5), is a trace constituent in the stratosphere and is produced by the photodecomposition of molecular oxygen.) The (ClO, Cl) chain therefore leads to a net ozone-loss reaction (Equation 6):

\[
O_3 + O \rightarrow 2O_2
\]  

An alternative pathway is Equation (4) followed by Equation (7):

\[
ClO + ClO \rightarrow 2Cl + O_2
\]  

Here again a (ClO, Cl) chain is involved and the net reaction is given by Equation (8):

\[
2O_3 \rightarrow 3O_2
\]  

(Only the overall stoichiometry has been shown in Equation 7. As discussed later, the reaction actually proceeds through the intermediacy of Cl2O2 and ClO2.) In this discussion, only reactions involving Cl have been shown; in reality a number of species such as OH, Br, and NO undergo reactions similar to Equations (4), (5), and (7), and play a significant role in ozone depletion.

From the above reaction scheme, it is clear that ClO is an important molecule in ozone depletion processes. Measurements have shown an increase in the ClO concentration over the polar stratospheric regions. It is therefore important to study the reactions of ClO with other species present in the atmosphere, so that the fate of the halogen monoxides in the atmosphere can be understood.

One such reaction is that between ClO and NO2 to form chlorine nitrate. This reaction is important where the NO2 concentration is high (Equation 9):

\[
ClO + NO_2 + M \rightarrow ClONO_2
\]  

(In this reaction, M is a third body that removes the energy of the complexed species and stabilizes it.) The chlorine nitrate is expected to photolyze only slowly in the UV. This reaction would tie up the ClO, by converting it into the less active ClONO2, referred to as a reservoir molecule. Equation (9) would therefore lead to a decrease in ozone depletion. However, there were speculations that this reaction may also produce a photolytically active isomer of chlorine nitrate, that may counter the reservoir effect. It was therefore important to study whether isomers of chlorine nitrate are produced by Equation (9). Burrows et al. addressed this problem using MI/IR spectroscopy, where they studied the reaction between ClO and NO2 by photolyzing flowing mixtures of Cl2, Cl2O, and NO2 and trapping the reaction product in an
N₂ matrix. The following Equations (10–12) were driven during photolysis:

\[
\text{Cl}_2 + h\nu \longrightarrow 2\text{Cl} \tag{10}
\]
\[
\text{Cl} + \text{Cl}_2\text{O} \longrightarrow \text{ClO} + \text{Cl}_2 \tag{11}
\]
\[
\text{ClO} + \text{NO}_2 + \text{M} \longrightarrow \text{product} \tag{12}
\]

The find product formed in these reactions was then trapped in a nitrogen matrix and the IR spectrum of this product was compared with synthetically produced ClONO₂. It was observed that the product spectrum agreed well with the spectrum of synthetically produced ClONO₂ and no extra features were seen that could be assigned to an isomer of chlorine nitrate. It was therefore concluded that Equations (9) and (12) do not give rise to any isomer of ClONO₂. The hypothesis of the existence of a photochemically labile isomer of chlorine nitrate that could alter the ozone depletion scenario was therefore discarded.

In environments where NO₃ abundances are low, the formation of chlorine nitrate (Equation 9) may be unimportant and alternate reaction pathways for ClO may dominate. Where the ClO concentrations are high, the self-reaction (Equation 7), may be significant. Such conditions appear to exist in the stratosphere over Antarctica. Although the net products are Cl and O₂, Equation (7) is believed to occur through the intermediacy of Cl₂O₂ and ClO₂ (Equations 13–15):

\[
\text{ClO} + \text{ClO} + \text{M} \longrightarrow \text{Cl}_2\text{O}_2 \tag{13}
\]
\[
\text{Cl}_2\text{O}_2 + h\nu \longrightarrow \text{Cl} + \text{ClO} \tag{14}
\]
\[
\text{ClO} \longrightarrow \text{Cl} + \text{O}_2 \tag{15}
\]

The species produced in the above reactions, Cl₂O₂ and ClO₂, have been the subject of a number of MI studies. The structure, spectroscopy and reactions of the dimer, Cl₂O₂, have been studied in great detail. Following these studies, it was found that the ClO dimer exists in three isomeric forms (structures (1–3)):

\[\text{ClO} - \text{O} - \text{Cl} \]
\[\text{Cl} - \text{O} - \text{Cl} - \text{Cl} \]
\[\text{Cl} - \text{O} - \text{Cl} - \text{O} \]

The most stable of these forms were structures (1) and (2), which were of comparable energy, whereas structure (3) was the least stable. Johnsson et al.,(28) Jacobs et al.,(29) and Cheng and Lee(30) trapped the ClO dimers in an argon matrix and showed that these forms can photochemically interconvert before eventually decomposing to yield the products, O₂ and Cl as given in Equation (7). These studies also established the different photolysis channels of these species, information that was required to establish the fate of the ClO dimer in the atmosphere.

Likewise, ClO₂ has also been the subject of MI investigations,(32,33) Two different structures are possible for this species, OCIO and ClOO. Both these isomers play an important role in stratospheric chemistry. The species CIOO is believed to be the primary photolysis product of CIOOCl, which then eventually dissociates to yield Cl and O₂, whereas OCIO is suggested as an intermediate in reactions involving CIO and BrO. Muller and Willner(32) isolated both these isomers of ClO₂ in argon and neon matrices and studied their vibrational and electronic spectra. They also showed that OCIO, when irradiated with a medium-pressure Hg vapor lamp (λ ≥ 395 nm), converted to CIOO. The MI studies described above(28–33) therefore revealed the intricate details of Equation (7).

It may be recalled that an analysis of the upper troposphere using MI spectroscopy indicated the presence of carbonyl halides (section 4.1.1). The carbonyl halides were believed to be formed by the oxidation of halocarbons in the troposphere. In an effort to understand this oxidative process, MI studies were conducted to probe the reaction of oxygen atoms with halocarbons. Schriver et al.,(34,35) have studied the reactions of compounds such as CC₁₂F (Freon 11) and CH₂Cl with oxygen atoms produced by a photolytic decomposition of ozone. Among other products, they observed the formation of carbonyl halides such as COFCl, which was one of the species identified by Wilson et al.,(15) in their analysis of the upper tropospheric samples. The experiments of Schriver et al. mimicked the oxidation of the halocarbons in the troposphere.

MI spectroscopy has been used in elucidating a number of these reactions to understand the atmospheric processes.

5 CONCLUSIONS

The technique of MI in conjunction with IR, fluorescence, and ESR has been used to address problems in atmospheric chemistry. Trace constituents in tropospheric and stratospheric samples have been measured, information that has proved useful in atmospheric modeling. Air samples from nearer to the earth’s surface have also been analyzed to estimate chemically hazardous materials that can potentially affect the local ecology of a place. The technique of GC/MI/FTIR used for these analyses is particularly useful for isomer-specific detection of chemically hazardous materials. In these applications, GC/MI/FTIR even scores over other more sensitive techniques, such as MS. MI has also been used to study the structure,
spectroscopy, and chemistry of reactive species that play an important role in the chemistry of the atmosphere.

1 INTRODUCTION

The requirements of industry and legislation take advantage of the qualities of chemical sensors and especially fiber optics and/or planar waveguide transducers, using their capability to continuously report changes of a physical parameter or the concentration of an analyte and the sensor’s ability to work reversibly. Industry discovered that chemosensors could be used for applications in process control, work place monitoring, and to follow legislation which requires threshold values for air, water, and industrial production to be met. Thus, demand for sensors has increased. These devices combine the properties of physical sensors (transducer) with the advantages and problems of chemical sensitive layers, by being responsible for the special properties of chemical sensors.

In the following, the properties of such optical sensors are discussed, they are classified according to certain characteristics and then the peculiarities of chemical sensing layers are considered. Since the definitions and general descriptions of sensors have been given in many reviews and books in recent years, just some of the special considerations regarding the optical chemical sensors applied to detect gases are given here. The main topics are the discussion of the chemical sensing layers and their present status of suitability, recent applications, and some trends in development and application to real-life situations in addition to modern analytical tools.

1.1 General Properties of Optical Sensors

An ideal sensor is sensitive, allows remote sensing and analysis in real-time, is economically priced, robust, reliable, cheap in maintenance, miniaturized, and simple to handle. Furthermore an ideal sensor is selective, has a high operational stability, has a wide dynamic range, and shows no drift of the baseline. Whereas the first of the mentioned prerequisites of an ideal sensor nowadays can be fulfilled by several transduction principles, the latter represent the remaining challenges in the field of chemical sensing. Most of these named restrictions are caused by the limited properties of the sensing element or sensitive layer.

One approach to overcome the limited selectivity of chemosensors is the application of chemometrics or pattern recognition. However, these techniques often require defined boundary conditions, which unfortunately are seldom found outside the researcher’s laboratory. This explains why, besides the optimization of the transduction principles, great efforts are taken in order to find the ultimate sensitive layers.

Light interacting with matter can yield a lot of different information about conditions of matter at high speed. Absorbance, luminescence, polarization,
interference, time, and wavelength (frequency), to name some examples, are measurements which can be interrogated by optical techniques. Optical sensors are generating increased interest due to several advantages such as remote sensing capabilities, no interference by electric or magnetic fields, and use in a wide area of applications, e.g. medical diagnostics. Due to this growing interest in optical sensors, a large number of publications and review articles have been published. Therefore it is not possible, or the intention, to give here a complete overview of this wide and growing area of fiber optic and waveguide gas sensors. Accordingly, this article is restricted to certain aspects and new developments have not been reviewed in detail up to now. Therefore we want to emphasize that nonquotation of a paper does not give any judgement about its quality. For a detailed survey, one should refer to the volumes of the monograph Chemical and Biochemical Sensors edited by Göpel et al., which also gives a detailed insight into optical sensors. A review covering chemical sensors from 1 December 1993 to 30 November 1997, with more than 900 references, was published recently. Fiber optic sensors (FOS) are well represented by several monographs and reviews. Additionally, a detailed overview of infrared (IR) FOS is given by Saito and Kikuchi. The development of liquid core optical fibers is discussed by Altkorn et al.

Thus we will focus on certain techniques of optical gas sensors such as devices like surface plasmon resonance (SPR), planar waveguide sensors, FOS, and reflectometric interference spectroscopy (RIIS). Only recent developments in gas sensing will be discussed here.

1.2 Classification of Optical Sensors

Besides the technique (SPR, FOS), optical sensors can be classified by their waveguide optics and the analytical way to detect the analyte and the modulated parameter of light leading to a three-dimensional classification. Whereas two dimensions, namely the detected parameter of radiation and the waveguide optics, are defined by the transduction principle and set-up of the device, the third axis is defined by the interaction the analyte experiences in the sensitive layer (Figure 1). We will not follow the scheme represented here strictly, but we consider it as a useful tool to classify the different methods, approaches and optics in the overall picture of optical sensors. A more detailed discussion of the following explained terms, which are used to classify the different types of FOS, is given by Boisde and Harmer and Potyrailo et al.

In general, fiber optical and planar waveguide sensors use the same principle; they guide electromagnetic radiation by internal reflectance. They differ in geometry and in fields of application. Therefore, in the following, fiber optics and planar waveguide structures will be used synonymously and called waveguides in general. The first are in many cases preferably used to just transport radiation. Both can be applied to monitor influences on this guided radiation, in addition. Accordingly, in the figure both types are marked on one of the axes. Additionally, optical sensors can further be distinguished by the terms extrinsic or intrinsic. In extrinsic sensors, radiation is just transported by the waveguide, is modulated outside the waveguide, and will re-enter the waveguide to be re-transported to the detector. The waveguide is simply used to transport the light to the sampling point and from there to the detector. In intrinsic optical sensors the light is not intended to leave the light-guiding structure to be modulated, rather the light-guiding structure itself represents the sensing element.

Influence on radiation can either cause a change in signal height, a shift in absorption maximum (frequency), a change in phase by shift in superposition of partial beams of radiation, a shift in the state of polarization, or a change in the time domain.

Direct detection is defined by the measuring of direct spectroscopic properties of the analyte or the sensitive layer influenced by the analyte, whereas indirect detection is defined by the detection of an analyte interacting with an additional reagent. The terms passive or reactive detection are used in the literature as well. Indirect detection often gives the opportunity to enhance the selectivity, but, on the other hand, further obstructions as effective immobilization or bleaching of a dye may
occur. The large amount of papers dealing with indirect detection is reflected by the efforts taken to find new selective chromophores,\textsuperscript{(20,21)} a collection about several applications and frontiers in analytical chemistry, sensor technology and the importance of near IR dyes herein is given in Daehne et al.\textsuperscript{(12)}

In the following text, first principles of operation of planar waveguide or FOS are given, then the principles of interaction between sensitive layer and analyte are discussed. Next, some applications are discussed for selected optical transduction principles.

2 FUNDAMENTALS

2.1 Aspects of Sensing in the Evanescent Field Region

Evanescent wave sensors are devices for the detection of refractive index changes of the sensitive layer $n_{sl}$ in contact with the waveguide, thus frequently called microrefractometers. These changes of $n_{sl}$ may be caused simply by sorption or by a chemical reaction. The sensitive layer is hereby a component of the light-guiding element, which can be a planar waveguide or fiber optics. The concept of intrinsic sensing is demonstrated in Figure 2 and will be discussed in a qualitative matter using FOS. Small diameter (<1 μm dependence on wavelength of guided radiation) of a waveguide results in monomode properties, larger diameters allowing multimode operation. For a more detailed discussion see Göpel et al.,\textsuperscript{(6)} Wolfbeis\textsuperscript{(8)} and Boisde and Harmer.\textsuperscript{(9)}

The properties of optical fibers depend on their numerical aperture and the critical angle of total reflection. Both of these depend on the refractive index of the core $n_{core}$ and cladding $n_{clad}$ of the fiber. Additionally, the numerical aperture depends on the refractive index of the surrounding medium as well. At each spot, where the guided light meets the interface between the core and the cladding, an electromagnetic field will be present on the side of the cladding, respectively, in the sensitive layer. This field is the so-called evanescent field, which penetrates into the cladding and the sensitive layer, depending on the refractive indices of the core and the cladding, respectively, the sensitive layer ($n_{sl}$, $n_{clad}$), and on the incident angle $\theta$ at the core/cladding interface. The penetration depth $d_p$ can be calculated with Equation (1):\textsuperscript{(9)}

$$d_p = \frac{\lambda}{2\pi n_{core}} \sin^2 \theta - \left( \frac{n_{core}}{n_{clad}} \right)^2 0.5$$  (1)

Analyte molecules sorbing into the sensitive layer will change $n_{sl}$ (if $n_{analyte}$ and $n_{sl}$ differ) and influence the evanescent field. This means that the sorbed analyte molecules modulate the light transmission properties of the fiber, which can be detected by a spectrometer or photodiodes.

Advantages of this intrinsic sensing concept are:

- no interrupted optical path, therefore an effective light budget;
- distributed sensing;
- many different transducers available, direct and indirect sensing possible;
- if $d_p < d_{sl}$, no cross-interference with substances outside the sensitive layer.

The parameters such as numerical aperture of the fiber, monomode or multimode fiber, wavelength, and thickness of the sensitive layer\textsuperscript{(22)} must be chosen with care, in order to ensure that the penetration depth $d_p$ will not become greater than the thickness of the sensitive layer. For applications in the middle IR region, this aspect is of special interest, since $d_p$ is proportional to wavelength and $d_p$ is increasing considerably in the region of the critical angle.\textsuperscript{(22)} An increase of the sensitive layer’s thickness would increase diffusion times of the target molecule and hence decrease the sensor’s performance.

2.2 Sensitive Layers

In recent years a lot of different materials have been investigated in order to enhance sensitivity and selectivity of the sensitive layers. A new approach to mimic antibodies is imprinted polymers,\textsuperscript{(21,24)} whereby the most promising examples achieving specific detection were demonstrated in liquid phases. Additionally, cyclohexapeptide,\textsuperscript{(25)} porphyrins,\textsuperscript{(26,27)} phthalocyanines,\textsuperscript{(28,29)} tailored polymers,\textsuperscript{(21,30–32)} sol-gels\textsuperscript{(33–36)} and organically modified
silicates\(^{37,38}\) (ormosils) were the focus of several publications.

### 2.2.1 Aspects Influencing Sorption

It will be of importance to obtain highly selective matrices, which are used to enrich the analyte molecules or to bind receptor molecules like dyes. For in doing so a profound understanding of the sorption of analytes in polymeric, sol-gel or other layers, which will be referred to as sensitive layers in the following text, is necessary. The sorption of an analyte molecule into a sensitive layer can be separated schematically in at least three processes:

1. adsorption onto the surface of the sensitive layer;
2. phase transition and diffusion from the outer surface into the sensitive layer’s bulk;
3. subsequent physical interactions with the sensitive layer.

Another process will take place, if the analyte molecule has chemical interactions with certain reaction sites present in the sensitive layer (Figure 3).

### 2.2.2 Boiling Point Dependency of Sorption

Sometimes the dependence of sorption on boiling point is misinterpreted as size selectivity of the sensitive layer. However, the energy needed to cause the phase transition from the adsorbed state to the gas phase increases with lower vapor pressure. If no real size-selective properties of the matrix or sensitive layer exist, e.g. as found in zeolites\(^{39}\) or polyimides\(^{40}\), the sorption of analytes for direct detection can be described in the following way.

A scale for the enrichment of a compound \(i\) is the partition coefficient \(f_i\), which is the ratio of the concentration of the analyte molecule in the sensitive layer \(c_{sl}^i\) and the concentration in the gas phase \(c_{g}^i\) as shown in Equation (2):

\[
f_i = \frac{c_{sl}^i}{c_{g}^i} \tag{2}
\]

Nonpolar analytes interact with the chosen sensitive layer in a similar way. Then \(f_i\) will increase with decreasing vapor pressure. Taking Picet–Trouton’s rule, which is valid in a homologous series, the boiling point \((T_b)\) dependence of \(f_i\) for the analyte \(i\) can be estimated\(^{41}\) according to

\[
\log f_i = 4.8 \frac{T_b}{T} - 4.8 + 0.43 \frac{\Delta S^{0,m}}{R} \tag{3}
\]

where \(\Delta S^{0,m}\) is the standard entropy of mixing. Equation (3) shows that the vapor pressure of a substance is governing the enrichment of a substance within a sensitive layer, if no subsequent chemical interactions occur.

### 2.2.3 Further Factors Affecting Enrichment

Attractive forces between analyte molecules and the sensitive layer can cause additional effects. Besides Coulomb forces, permanent dipole–dipole, induced dipole–dipole, and dispersion forces are discussed. In addition, hydrogen bonds will increase the interaction between analyte and sensitive layer. For these kinds of interactions the chemist’s rule of thumb “like dissolves like” may be used to choose which sensitive layer is an appropriate choice for a certain analyte, in order to achieve high partition coefficients.

Furthermore, the analyte molecule may undergo chemical reactions at reaction sites present in the sensitive layer (see steps 3 \(\rightarrow\) 4 in Figure 3) enhancing the sensitivity and selectivity. A typical example of such a reaction is the reaction between an acidic or basic molecule and an indicator dye entrapped in the sensitive layer.

---

**Figure 3** Sorption steps of an analyte molecule: (1) adsorption onto sensitive layer; (2) phase transition and diffusion from the surface into the bulk; (3) subsequent physical interactions; (4) diffusion to reaction site (physically or chemically trapped in the polymer) with chemical interaction.
is an extrinsic FOS system detecting modulations in the wavelength region, and allowing direct and indirect analyte detection.

3.2 Principle of Reflectometric Interference Spectroscopy

Spectral interferometry measures the interference pattern caused by the superposition of two reflected partial beams at parallel interfaces of a thin layer. Spectral interferometry depends on the refractive indices of the film, the thickness of the film, the wavelength (preferably in the optical region 400–700 nm), and the angle of incidence of radiation.

The principle set-up depicted in Figure 4 consists of a white light source, Y-fibers, the sensing element, and a diode array spectrometer. The signal is measured relative to a coated (noncoated) substrate $I_r$ ($I_{ref}$), according to Equation (4). $I_0$ represents the blank or zero signal.

$$I = \frac{I_r - I_0}{I_{ref} - I_0}$$

If an analyte sorbs into a polymer film, the film will change its optical thickness $nd$, where $d$ is the physical thickness and $n$ the refractive index of the sensitive layer. A more detailed description of the principle and evaluation of RIIS is given by Kraus and Gauglitz.345 Because of the coherence condition of white light and the interference condition, the film thickness of that layer, where the sensitive coating builds up the interference layer, has to range between 300 nm and 30 µm. However, if the sensitive coating is attached to a solid SiO$_2$ layer acting as basic interference layer, even sorption on to monolayers can be investigated.25,46

3.3 Applications

The response of a polymer like poly(dimethylsiloxane) (PDMS) versus several VOCs as $n$-pentane to $n$-octane or chlorinated hydrocarbons is described by Gauglitz et al.46 Films thinner than 1 µm yield response times less than 1 s. For tetrachloroethene a detection limit in the ppm range was found and the sensor response was linear up to 10 000 ppm. Since the PDMS-based sensor showed high cross-sensitivities against the mentioned VOCs, it became obvious that a multisensor set-up and subsequent chemometrics47 must be used, in order to overcome this limitation in the analysis of mixtures. Artificial neuronal networks44 and partial least-squares regression methods48 were applied to discriminate binary or ternary VOC mixtures. The sorption behavior of different VOCs in five different polymer-based sensitive layers with and without relative humidity was investigated.

Based on these considerations, great effort was made to find sensitive layers with higher selectivities. For
cyclohexapeptides, which proved to be highly selective for certain amino acids in aqueous phase,\(^{(49)}\) it could be verified that the analyte’s permittivity plays a major role besides the analyte’s vapor pressure for the resulting sensitivity. Similar selectivities to those in the aqueous phase towards different VOCs,\(^{(50)}\) could not be found in the gas phase.

The detection of basic or acidic substances with optic gas sensors is usually accomplished by physical or chemical entrapment of an indicator dye in a sol-gel or polymer matrix. As long as the optical properties of the indicator dye will not change in an unexpected way, covalent linking of the dye is advantageous, since diffusion or leaching of the dye can be prevented. One major drawback of indicator dyes is due to photobleaching,\(^{(13)}\) which limits the operational stability of the sensor. pH-responsive polymers allow the dyeless optical detection of basic or acidic substances by covalent incorporation of acidic or basic functional groups in the polymer matrix. Analyte-induced deprotonation of these functional groups leads to additional uptake of water by the polymer. Using a modified polysiloxane\(^{(32)}\) with carboxylic acid end-groups, detection limits below 200 ppb could be determined for ammonia. The signal decrease was 30% in 68 days. During this time period the sensor was continuously exposed to white light and synthetic air (20.5% \(O_2\) in \(N_2\)). A dye doped sol-gel layer exhibited a 40% decrease of the signal under identical boundary conditions within 10 h. Drawbacks were the long response time and the influence of relative humidity on the sensor’s signal.

In principle, achieving chiral discrimination by gas sensors is more difficult than by gas chromatography (GC), because the sensor uses only one “theoretical plate” (one adsorption/one desorption step). In contrast, using GC discrimination typically results from thousands of successive adsorption/desorption equilibria. Nevertheless Bodenhöfer et al.\(^{(50)}\) successfully demonstrated the separation of optical enantiomers using QMB and RIIS. \(S\)- and \(R\)-octyl-ChiralSIL-Val were used as selective coatings, and the enantiomers of \(N\)-trifluoroacetyl-alanine-methylester (TFA-Ala-OMe) were used as analytes. Both sensors, the \(S\)- and \(R\)-type, showed identical signals when exposed to the racemic mixture of TFA-Ala-OMe; however, there was little increase in signal height for the equivalent isomer.

### 4 FIBER OPTIC SENSORS

The term opt(r)ode is commonly used to name sensor systems, wherein optical fibers are taken. Both terms were defined by Lübbers. Optode\(^{(51)}\) is derived from the Greek, meaning the “optical path”, whereas optrode\(^{(52)}\) stands for “optical electrode”. Since the applications for FOS, especially indirect FOS, are extensively covered in the literature (see section 1), the theory will only be handled in brief. Only recent applications will be considered. A description of interferometric noise is given by Jin et al.\(^{(53,54)}\) and may prove useful for the design of a particular fiber optic gas sensor, since interference between signal radiation and reflected radiation can cause signal fluctuation in the output, which can limit the performance of the sensing system. By the application of gas-permeable membranes,\(^{(55)}\) FOS are easily adapted for liquid sensing.

#### 4.1 Extrinsic Sensing Applications

##### 4.1.1 Extrinsic Direct

Dasgupta et al.\(^{(56)}\) presented a new long-path optical transmission cell for fiber optic absorbance measurements, which is a liquid core fiber optic waveguide. The cladding of this waveguide is simply a hollow polymer tube. Since the polymer’s refractive index is \(<1.333\), water can be used as the core of the fiber. The fluoropolymer used has a three times higher gas permeability with respect to poly(tetrafluoroethylene)-type Teflon\(^{(57)}\), therefore the fiber shows potential for chemical sensing in the liquid and gaseous phases. A FOS for smoke measurements was presented by Matias et al.\(^{(57)}\) The sensor works based on the following principle: diesel engine particulates get stuck on a gluing surface of a white tape, changing the diffuse reflectance of the tape’s surface. Response times in the range of 0.1 s were reported. Different types of extrinsic sensing configurations are schematically shown in Figure 5.

##### 4.1.2 Extrinsic Indirect

Cardoso et al.\(^{(58)}\) described a highly sensitive fluorescence-based extrinsic indirect FOS for the detection of atmospheric \(H_2S\) in the ppb\(_v\) range. A drop of

![Figure 5](image)

**Figure 5** Different measurement configurations for extrinsic fiber optic sensing. (a) Indirect, end of fiber; (b) direct, end of fiber; (c) indirect, transmission; (d) extrinsic, direct, transmission.
alkaline fluorescein acetate solution is suspended in a flowing air sample stream. As H₂S in the sample is collected by the alkaline drop, it reacts rapidly with the fluorescence dye, resulting in a significant decrease in fluorescence. Tabacco et al. modified an indirect CO₂ sensor with a gas permeable membrane for measurements in seawater. The sensor exhibited a reversible working range between 200 ppm and 1000 ppm PCO₂. Selective opt(ri)ode membranes were presented by Spichiger-Keller for the detection of ethanol and CO₂ in bioreactors.

4.2 Intrinsic Sensing Applications

The principle of sensing in the evanescent field region has already been shown in Figure 2. Additionally, typical sensing configurations are depicted on Figure 6. In the normal fiber arrangement, part of the cladding is removed to allow the evanescent field to be directly in contact with the sensitive layer either in a transmission mode (Figure 6a) or in reflection (Figure 6b). Another approach is to bend the fiber at the region coated with the sensitive layer (Figure 6c). This may lead to a significant increase of the sensitivityhowever, the system becomes sensitive to mechanical disturbance.

4.2.1 Direct Intrinsic

A porous sol-gel layer was used in order to detect analyte-induced changes of the refractive index. The detection limits of different alkanes and halogenated hydrocarbons were in the range between 0.6% and 25%. An ozone sensor was described by Potyrailo et al. with good stability over a 2-month period of investigation and a linear response between 0.02 vol.% O₃ and 0.35 vol.% O₃. The response proved to be reversible with a time constant of 1 min. It is noteworthy that these investigations were performed in the near ultraviolet (UV) region (at 254 nm), whereas most published investigations for evanescent field sensing are either in the visible or near and mid IR wavelength region. Attenuated total reflection IR/FOS can be classified as direct intrinsic sensors as well.

A multipoint sensor system is described in Stewart et al. for methane detection along a long fiber using optical time-domain reflectometry (OTDR). A short light pulse is coupled into the fiber and transported by total internal reflection. A certain amount of the light will be back-scattered at the fiber’s end and can be recorded by a fast detector resolved with time. This allows localization of any effect (laterally resolved) within the cladding of the fiber by the time delay between the excitation pulse and the received back-scattered signal (change in the effective refractive index at a point causes partial back-scattering of the guided radiation). This is a well-known technique to characterize fiber optic networks. An overview of the possible applications with direct and indirect signal modulation was recently given by Sensfelder et al. One limitation of the OTDR technique is the loss of light guiding capabilities, if the refractive index change reaches such an extent that the out-coupling of radiation damps the propagating radiation. Thus no information can be obtained about effects beyond this point.

4.2.2 Indirect Intrinsic

An indirect intrinsic fiber optic evanescent field sensor based on near IR dyes was reported by Malins et al. Methyl and ethyl derivatives of a 5-(4′-di-alkylaminophenylimino)-quinolin-8-one copper(II) perchlorate complex were immobilized in a thin poly(vinyl chloride) matrix coated on an optical fiber with 600 μm diameter. Ammonia in the range between 10 ppm and 100 ppm was investigated. The sensor showed response (recovery times) of the order of 30 to 40 s.

UV-curable ormosils have been synthetized by the sol-gel method and used as sensitive layer for silica optical fibers. The refractive index of the coating could be tailored in the range between 1.46 and 1.56. The sensitivity versus CO₂ could be enhanced by the introduction of amino groups into the polymer.

A humidity sensor based on a hydroxypropylcellulose film doped with Rhodamine B was presented by Taguchi et al.

5 PLANAR WAVEGUIDE SENSORS

5.1 Introduction

An illustrative insight into the field of integrated optics (IO) and planar or slab waveguides is given by Göpel et al. and Boisidé and Harmer. IO comprises several benefits such as ruggedness, miniaturization, construction on a chip, high sensitivity, and remote sensing capabilities.
since IO parts can efficiently be linked to fiber optics. Planar waveguides are frequently used for intrinsic sensing in the evanescent field region by the use of grating couplers and polymers acting as sensitive layers. IO grating couplers were proposed by Tiefenthaler and Lukosz\(^6\) in 1987.

Planar waveguides can be classified as a film waveguide (thin layer on top of a substrate) or a strip waveguide (often called a slab waveguide). A slab waveguide can be described in the most simple form as a dielectric layer with the refractive index \( n_1 \) matched in-between two layers, the substrate and the superstrate layer, with the refractive indices \( n_0, n_2 \), where \( n_1 > n_0, n_2 \). Some variations of the set-up of planar waveguide configurations are depicted in Figure 7.

Since a proper theoretical discussion of the influence of the waveguide structure is far beyond the scope of this review, we want to refer to the already mentioned monograph by Göpel et al.\(^6\) and references therein. Shortly, the sorbed analyte will directly or additionally indirectly vary the refractive index of the sensitive layer, thereby either modulating the transmission of the guided light or reflectance properties of a grating. Usually the light source is a laser and will be coupled into the waveguide by a grating, a prism\(^\text{68}\) or a gradient index fiber.\(^\text{69}\) Chirped waveguide gratings\(^\text{70}\) simplify the conditions to meet the coupling conditions. Several concepts of the IO refractive index sensing systems are described by Kunz.\(^\text{71}\)

Another approach uses interference between two waveguide arms forming a Mach–Zehnder type arrangement.\(^\text{72}\) One of the waveguide arms is coated by polymer or any other sensitive layer, the other is a reference arm. Reduction of propagation velocity in the first arm causes phase modulation of the signal monitored after reunification of both radiation pathways (see Figure 8).

### 5.2 Applications

An integrated optical absorbance sensor for the detection of trichloroethene and tetrachloroethene in the near IR wavelength region was described by Burck et al.\(^\text{69}\)

As frequently applied in FOS, the incorporation of indicator dyes into a sensitive layer is used for the detection of acidic or basic analytes. An example is given by Brandenburg et al.\(^\text{73}\) for the detection of ammonia. Bromoresol Green and Bromphenol Blue were immobilized in a silicone matrix. Concentrations less than 1 ppm were detectable with a dynamic range up to 20 ppm. Acidic gases were found to reduce the relative change in signal.

Iodine gas can be detected by the formation of charge-transfer complexes between iodine and phenyl groups, which were incorporated in a methylated glass film.\(^\text{74}\) A linear response was obtained in the range between 100 ppb and 15 ppm, with response and recovery times less than 15 s.

A coupling wave optical waveguide was presented by Qing et al.\(^\text{33}\), which proved to be very sensitive versus H\(_2\)S. The feature of this sensor is that the one waveguide can be adjusted for light guiding and the other for sensing.

![Interaction with analyte](image)
Thin films of RbCl and AgCl were used as sensitive films on a planar optical waveguide to sense chlorine with a measurement range from $3 \text{ ppm}$ to $1.5\%$.\textsuperscript{75}

The properties of a nematic liquid crystal as a sensitive layer for VOCs were investigated by Drapp et al.\textsuperscript{76} Therein it was demonstrated that the analyte-induced phase transition of liquid crystalline systems can lead to enhanced sensitivities and selectivities.

6 SURFACE PLASMON RESONANCE SPECTROSCOPY

6.1 Introduction

SPR spectroscopy is a frequently used technique in biosensor technology.\textsuperscript{77} The great demand for a marker free transducer system is reflected by the appearance of commercially available systems like the Swedish Biacore AB, launching the first commercial SPR biosensor in the market in 1990. Another commercial SPR system was introduced by Texas Instruments (called TI-SPR-1) with bi- and chemosensing capabilities in liquid phases.\textsuperscript{78} Liedberg et al.\textsuperscript{79} pioneered SPR spectroscopy in the field of chemical sensors in 1983. However, the amount of publications concerning chemosensors is well below the amount of publications concerning the biosensor field. Forgenson and Yee\textsuperscript{80} introduced the fiber optic evanescent field to SPR spectroscopy in 1993. Miniaturization and parallelization of the transducer can be achieved by integrated optic devices. The use of fiber optics and integrated optic devices would enhance the remote sensing capabilities, allow multiple component analysis and probably reduce the wide gap between the laboratory and field applications. A survey of trends in SPR was recently given by Homola et al.\textsuperscript{81} With respect to the terminology discussed in section 1.2, SPR spectroscopy is a direct intrinsic sensing method.

6.2 Principle of Surface Plasmon Resonance

A plasmon wave is a collective excitation of the electron gas in a metal.\textsuperscript{82} There exist two different kinds of surface plasmons depending on the excitation conditions, radiating and nonradiating surface plasmons. Whereas volume and radiating surface plasmons\textsuperscript{83} have to be excited by UV light, nonradiating surface plasmons\textsuperscript{84} can be excited by polarized visible light. The latter case exists for the applications given. No further distinction between the different kinds of the surface plasmons will be made in the following text.

The total reflection of light, occurring at a phase boundary (e.g. between the prism coupler and a metal film), is accompanied by the origin of an evanescent field, which penetrates the metal film. If the energy of the evanescent field is meeting the resonance condition for surface plasmon waves in the metal film, the reflected light will experience an attenuation. The metal film has usually a thickness of around $50 \text{ nm}$.\textsuperscript{85} The surface plasmon wave is a resonant phenomenon that depends on the index of refraction and the thickness of the metal film, as well as on the index of refraction of the adjacent medium containing the analyte (and a sensitive layer, respectively). The resonance condition to excite a surface plasmon can be met by either varying the angle of incidence $\theta$ or wavelength $\lambda$ of radiation.

SPR measurement techniques are based on the detection of modulation of the intensity,\textsuperscript{79,86} the angle,\textsuperscript{78,87,88} the wavelength, leaky modes\textsuperscript{89} or by phase modulation of the reflected light.\textsuperscript{90,91} The detection of the pure intensity, which is based on a measurement set-up with fixed angle and wavelength, is less desirable, since it cannot be determined whether the signal change is caused by a change of $n$ or whether experimental errors are responsible. Common experimental methods are in principle based on angle or wavelength modulation. An elegant set-up for angle modulation, without any components in motion was accomplished by Melendez et al.\textsuperscript{78} Wavelength modulation does not require moving instrumental components, simplifying the experimental conditions and enhancing reproducibility. A further method is based on the detection of the phase modulation.\textsuperscript{90} Since surface plasmon waves can only be excited by transversal magnetic modes (plane of polarization parallel to the plane of incidence) excitation of surface plasmon waves will cause a detectable phase shift between reflected transversal electric (perpendicularly polarized) and transversal magnetic polarized light.

6.3 Measurement Set-ups

In contrast to the Otto type, which excites surface plasmons by visible light at the base of a prism with a short distance to a metal surface,\textsuperscript{92} Kretschmann pursued another strategy.\textsuperscript{93} The thin metal layer is directly coated on to the base of a dielectric. The plasmon is excited at the opposite surface of the metal film close to the analyte or a sensitive layer as demonstrated in Figure 9.

**Figure 9** Typical Kretschmann configuration.
A modification of the Kretschmann configuration was described recently by Homola and Yee. The use of two crossed polarizers with a 45° orientation to the plane of incidence and a phase retarder allow the detection of the surface plasmon as a peak, which may be advantageous if the usually detected resonance minimum is adversely affected by, say, an analyte-induced optical nonhomogeneity.

In the original set-up the high refractive index material was a prism, but it can also be the core of a fiber or the window of a planar waveguide. The fiber optic SPR set-up is simpler than the classical Kretschmann set-up. The prism and the ray trace is replaced by a Y-fiber optical waveguide as schematically shown in Figure 10. The reference spectra are recorded by measuring the reflectance spectra of the fiber with the bare metal film (without sensitive layer). No particular care needs to be taken with regard to the coupling of light into the prisms. In contrast to the Kretschmann configuration, where just one reflection occurs, waveguide SPR increases the signal by taking advantage of multiple interactions along the length of the metal layer. Waveguide sensing devices are therefore simple, easy to handle, usable as probes or for remote sensing.

Integrated optical SPR sensors based on planar waveguides have several benefits: small size, ruggedness, the fact that multichannel sensors on a single chip are possible, with all this being combined with fiber optics remote sensing capabilities. A design tool for a multilayer set-up to calculate the transmission characteristics of planar waveguide SPR sensors is described by Harris and Wilkinson. The device shown in Figure 11 demonstrates the multilayer approach.

A variant of the planar waveguide set-up was developed by Karlsen et al. and Homola and Yee. A measurement set-up with multicomponent chemical analysis capabilities was proposed, based on a planar light pipe, which allows the reflectivity to be determined as a function of wavelength for a set of angles of incidence. The detection of phase shift between transversal magnetic and transversal electric polarized light was introduced by Nelsen et al. and has a high calculated resolution for Δη (0.5 × 10⁻⁶), which could not be verified experimentally. Additionally, it must be noted that the experimental set-up for the detection of phase modulation amounts to as many as 21 components.

### 6.4 Applications

Since SPR spectroscopy detects changes of the refractive index, the sensitivity is not only governed by sorption effects, but in addition the difference between the refractive indices of the analyte and the sensitive matrix has to be taken into account. Furthermore, the insufficient stability of the silver layer against oxidation or hydrogen sulfide must be solved in order to achieve a high operational stability of the sensitive layer under real conditions. This is commonly achieved by the use of alkylthiols as self-assembled monolayers (SAMs). Niggemann et al. obtained an operational stability of 3 months, with an identical sensitivity of the PDMS layer. The response time of the sensor was in the range of 2.5 s and the detection limit was estimated to be 15 ppm.

Abdelghani et al. used a fluoroalkoxysiloxane polymer and alkylthiol SAMs as well. The observed limits of detection for chlorinated hydrocarbons were still in the low percent range (C₂HCl₃, 0.3; CCl₄, 0.7; CHCl₃, 1; CH₂Cl₂, 2). However, coating the silver or gold layer will not solve all the problems, according to Schoenfisch and Pemberton. They found that the sulfur–metal bonding is oxidized under ambient conditions. It was proposed that ozone is responsible for the observed oxidation process.

Besides the detection of VOCs with sensitive layers on polysiloxane bases, the detection of NOx with porphyrin-based sensitive layers is described in several publications. Zhu et al. used a copper phthalocyanine Langmuir–Blodgett film to detect NOx gas. The limit of detection was in the range of several ppm, with unacceptably long recovery times for a practicable sensor. A selective NO₂ was described by Ashwell and Roberts. It exhibits few cross-interferences to 100 ppm SO₂, H₂S, Cl₂, CO, CO₂ and 10% deterioration after 1000 to 1500 adsorption/desorption cycles. Nikkitin et al. described an experimental set-up that allows combination of surface-enhanced Raman scattering (SERS) and SPR to detect NO₂ (limit of detection < 4 ppm). The recovery time was reported to be longer than 300 s. Furthermore, it was noted that the
sensing effect of the pure gold film may exceed the signals of the phthalocyanine-coated layers. A recent publication describes the enhancement of the sensitivity using a dye (1,1',3,3',3'-hexamethylindodicarbocyanine iodide) which contains a strong absorption band centered in the dynamic range of the SPR coupling wavelength.\(^{(104)}\)

Agbor et al.\(^{(105)}\) investigated a polyaniline-based sensor versus NO\(_2\) and H\(_2\)S with detection limits of 50 ppm. On the silver layer a thin nickel layer was deposited (1 nm Ni on top of 50 nm Ag) in order to prevent other gas effects on the silver layer.

### 7 SUMMARY

The review intends to demonstrate that a large variety of optical transduction principles exist and these provide some solutions to different analytical problems. Most of them employ similar sensitive materials, proving that the quality of the sensing device in most cases depends on the properties of the sensitive layer rather than on the transduction principle chosen. Certainly in the future there will be some improvements in the optical properties of the different devices.

The main interest in recent years has been dedicated to sensing-material that is more stable, more selective, demonstrates better response times and is tailored to suit the application. In this area, new materials and new approaches will attract the most interest. Problem-solving that related especially to synthesized polymer films that combine stability and inertness with some selectivity by functional groups, while keeping their reversibility will be well worth the efforts of chemists. The first publications testing approaches with liquid crystals and polymer backbones, as well as using molecular imprinted polymers, demonstrate these trends.

Scanning the literature for new developments shows the need to combine knowledge in optics with skill in polymer chemistry in order to create improved sensor devices. This fact simply takes account of the fundamental idea of a chemical sensor containing (in addition to a physical sensor) a sensitive layer which takes care of the chemical interaction between the analyte and the sensor and determines the properties of the sensor system.

ENVIRONMENT: TRACE GAS MONITORING

Photoacoustic Spectroscopy in Trace Gas Monitoring

Frans J.M. Harren, Gina Cotti, Jos Oomens, and Sacco te Lintel Hekkert
University of Nijmegen, The Netherlands

1 INTRODUCTION

A gaseous molecule that absorbs electromagnetic radiation is excited to a higher electronic, vibrational or rotational quantum state. Generally, depopulation of this quantum state to lower lying states occurs either via fluorescence or collisions, the latter giving rise to a temperature increase of the gas due to energy transfer to translation. This nonradiative relaxation process occurs when the relaxation time can compete with the radiative lifetime of the excited energy levels. Radiative decay has a characteristic lifetime of $10^{-7}$ s at visible wavelengths as compared with $10^{-2}$ s at 10 $\mu$m. For nonradiative decay these values depend on the pressure (decay time inversely proportional to the pressure) and can vary strongly at atmospheric pressures ($10^{-3}$ – $10^{-8}$ s).

By modulating the radiation source at an acoustic frequency the temperature changes periodically, giving rise to a periodical pressure change which can be observed as an acoustic signal; in the gas phase the effect can be detected with a sensitive microphone.

Laser-based photoacoustic detectors are able to monitor trace gas concentrations under atmospheric conditions with orders of magnitude better sensitivity than conventional scientific instrumentation; in addition they are able to monitor noninvasively and on-line under dynamic conditions.
measured trace gas absorption spectra with an infrared broadband light source down to the parts per million level.

By the end of the 1960s, after the invention of the laser, scientific interest increased once again. In 1968, Kerr and Atwood\(^8\) utilized laser photoacoustic detection to obtain the absorption spectrum of small gaseous molecules. Due to the high spectral brightness of lasers and improved phase-sensitive lock-in techniques that amplified the acoustic signal, they were able to determine low concentrations of air pollutants. Kreuzer\(^9\) demonstrated that it was possible to detect concentrations of e.g. 10\(^{-8}\) (10 parts per billion) of methane in nitrogen, using an intensity modulated infrared (3 \(\mu\)m) He-Ne laser. Patel et al. demonstrated the potential of the technique by measuring the NO and H\(_2\)O concentrations at an altitude of 28 km with a balloon-borne spin-flip Raman laser.\(^{10}\) After this the photoacoustic effect was introduced into the field of trace gas detection with environmental, biological and medical applications.

3 DEVICES AND EQUIPMENT

3.1 Light Sources

With reference to the previous paragraph, lasers are not essential to operate photoacoustic gas detection systems. Although the spectral power density of broadband infrared light sources is orders of magnitude lower compared with lasers, their advantages are reliability and cost effectiveness. Infrared light sources in combination with various photoacoustic detection schemes are commercially available for trace gas detection at parts per million levels. Spectral selectivity is achieved by using FTIR (Fourier transformed infrared) spectroscopy in combination with spectral band filters in front of the photoacoustic cell; thus typically seven molecular gases can be detected simultaneously at the 1–100 ppm level.

The URAS gas analyzer of Hartmann & Braun uses a photoacoustic detection scheme which is able to detect a specific gas out of a multicomponent gas mixture avoiding cross interferences. In this instrument selectivity is achieved by comparing the direct absorption in a sample cell to that in a reference cell. After passing the sampling cells, each attenuated light beam enters a second detection cell filled only with the gas of interest (Figure 2); the detection cells are interconnected via a membrane connected to a capacitor. Since the dual beam is modulated the difference in acoustic energy reflects the difference in absorption and thus the concentration difference between sample cell and reference cell. The species under investigation enables the wavelength to be selected in such a way that all wavelengths at which absorption occurs are simultaneously active. When there is no spectral overlap from other gases, additional absorptions in the sample cell will not contribute to the acoustic signal; the light passes the
Figure 2 Infrared gas analyzer of Hartmann & Braun with photoacoustic detection scheme to detect a specific gas from a multicomponent gas mixture thereby avoiding cross-interference. Light from the infrared source is split into two paths. The chopper modulates the intensity for both paths. A filter volume in each path serves to filter out light of wavelengths not needed for the detection process; they can be filled with gases whose absorption spectra do not overlap with those of the species under scrutiny. M1 and M2 serve as measuring cell and reference cell respectively. With the help of the equalizer both light intensities become equal before entering the last cell. The last cell consists of two compartments with a membrane between them. Both compartments are filled with the gas under investigation so that all wavelength characteristics for this gas contribute to the signal. If the attenuation differs in M1 from that in M2 the membrane starts to oscillate with the frequency of the chopper. This oscillation (typically a few hertz) is detected capacitively.

detection cell unattenuated. When a specific compound, e.g. H₂O, causes spectral overlap, an extra cell can be placed in the light path filled with the interfering gas. This cell completely attenuates the wavelengths where this interfering molecule absorbs, including the spectral overlap regions. Thus, these wavelengths cannot contribute to the photoacoustic signal and a single component of a complex multicomponent gas mixture can be detected.

High spectral brightness renders CW (continuous wave) laser sources ideally suitable for photoacoustic trace gas detection. In contrast to direct absorption techniques, the photoacoustic signal is proportional to the laser power; from the Lambert–Beer law one finds for small absorptions (Equation 1)

\[ P = P_0 e^{-\alpha N l} \Rightarrow (P_0 - P) \approx P_0 \alpha N l \]  

(1)

where \( P_0 \) and \( P \) are the laser power before and after the photoacoustic cell, respectively, \( \alpha \) is the absorption cross-section per molecule (in cm²), \( N \) is the number of absorbing molecules per cubic centimeters and \( l \) the absorption path length (in cm). The absorbed energy \( (P_0 - P) \) is converted into acoustic energy which is recorded by the microphone.

Saturation, due to nonlinear absorption of the laser power only occurs in focused high-power laser beams. The pumping rate to a higher rovibrational level is proportional to the laser light intensity; in the case of saturation it exceeds the collisional de-excitation rates.

Besides sensitivity, lasers achieve high selectivity. The spectral selectivity is only limited by the pressure broadened absorption profiles of the gases under investigation. The first practical lasers which were used to detect trace gases were CO₂ lasers. These line tunable lasers cover the infrared 9–11 μm wavelength region with a laser line spacing of 0.5–2 cm⁻¹. Fingerprint absorption spectra can be achieved if we compare the laser line spacing to the pressure broadened absorption lines for the trace gas molecules (typically a few gigahertz at atmospheric pressures). Additionally, they are able to deliver high laser powers (1–100 W) from a relatively small gas discharge tube.

A new development is the application of the CO laser in its \( \Delta v = 1 \) (5.0–7.6 μm wavelength region) and \( \Delta v = 2 \) (2.5–3.8 μm) version. Although less powerful (typically 1 W) its performance can be improved by applying an intracavity set-up. CO lasers are line tunable with a line spacing between 0.5–1 cm⁻¹.

Other CW lasers in the visible and infrared have been applied to photoacoustic trace gas detection such as a spin flip Raman laser, diode lasers and dye lasers. Although dye lasers and titanium sapphire do not cover the ideal wavelength region for trace gas detection they are very well suited for photoacoustic spectroscopy of weak absorption bands with their continuous tunability and a typical CW laser power of 1 W and they have proved their potential in molecular spectroscopy of highly vibrationally excited molecules. However, for trace gas detection they are less applicable since the overtone molecular absorption cross-sections are weak, thereby raising the detection limits. For the same reason infrared diode lasers derived from telecommunication research (0.8 and 1.5 μm) are not very well suited.

Of periodically poled nonlinear crystals that have been developed, periodically poled lithium niobate (PPLN) is probably most well known. Lithium niobate (LiNbO₃) can be used in combination with pulsed lasers to generate mid-infrared radiation (2–5 μm) by parametric oscillation. CW operation was limited to a few microwatts of laser power due to phase matching problems. Quasi-phase matching with periodically poled materials overcomes this problem resulting in laser powers up to a few watts in the infrared.

The advantage of using pulsed lasers for photoacoustic detection is their wider infrared tunability and consequently better spectral overlap with interesting molecular gases. Examples can be given of the experiments performed with a pulsed CO₂ laser by Repond and Sigrist and experiments with a pulsed optical parametric oscillator (OPO). A disadvantage of pulsed lasers is their high peak powers (megawatt) in relation to their relatively low average energy (typically 1 W) which has to generate a relatively slow process as the gas phase photoacoustic
effect. Peak-to-peak fluctuation and nonlinear absorption distortion the reproducibility of the generated signal, thereby raising detection limits. Typical detection limits reported with these types of laser are in the parts per million range.

### 3.2 Photoacoustic Cells

To perform trace gas detection the ideal photoacoustic cell should amplify the generated sound originating from the molecular gas absorption meanwhile rejecting acoustic (and electric) noise and in-phase infrared absorption from other materials. Interfering gases should be distinguished by spectroscopic or physical methods (see section 3.3).

For gas phase measurements, mainly resonant cells are combined with modulated CW lasers and lock-in amplifiers; pulsed lasers are combined with piezoelectric detectors and boxcars. These selective amplifiers arise from the necessity to lower acoustic and electric noise levels thus improving the signal-to-noise ratio.

Other requirements for photoacoustic cells are a low gas consumption or a fast response; for this the active volume of the cell should be small so that no dilution can take place when the trace gas and its carrier flow through the acoustic cell.

If we consider a nonresonant, cylindrical cell, its performance can be expressed as its efficiency to convert absorbed photon energy into acoustic energy; this cell constant $F$ (Pa cm W$^{-1}$)$^{21,22}$ is given by Equation (2)

$$F_{\text{nonresonant}} = \frac{G(\gamma - 1)L}{\omega V}$$  \hspace{1cm} (2)

where $L$ and $V$ are the length and the volume of the cell, respectively, $\gamma$ is the specific heat constant, $\omega = 2\pi v$ the modulation frequency and $G$ is a geometrical factor in the order of one. Within a nonresonant cell the gas absorption signal is independent of the cell length but inversely proportional to its diameter. However, photoacoustic signals are also generated by infrared window absorption. To reduce these signals inside the cell its length should be as long as possible to spread this locally generated sound over the total cell volume.

For a resonant cell, the above cell constant $F$ must be amplified with the quality factor $Q$ of the generated acoustic resonance, Equation (3)

$$F_{\text{resonant}} = QF_{\text{nonresonant}}$$  \hspace{1cm} (3)

where $Q$ is expressed by the ratio of the energy stored in the acoustical standing wave divided by the energy losses per cycle. This acoustical amplification process is limited by various dissipation processes which can be divided into surface and volume effects. Main surface losses are viscous and thermal losses at the resonator surface, microphone losses and acoustic wave scattering losses at obstacles in the cell. Volumetric losses are not as important as surface losses and are mainly due to free space viscous and thermal losses and $V - V$, $V - R$, $V - T$ relaxation losses of polyatomic gases.$^{1,23}$

A cylindrical cavity can be a resonant cavity for sound waves. The resonance frequencies of such a cavity are given by Equation (4)

$$f_{\text{res}} = \frac{v_s}{2\pi} \left( \frac{\alpha_{mn}}{2R} + \frac{p}{2L} \right)^{1/2}$$  \hspace{1cm} (4)

where $v_s$ is the sound velocity in the gas filling the cavity, $R$ is the radius of the resonator, $L$ is the length, $p = 0, 1, 2, 3 \ldots$ axial mode numbers and $\alpha_{mn}$ is a suitable solution of Bessel equations with $m = \text{radial mode number}$ and $n = \text{azimuthal mode number}$ (Figure 3).$^{124}$

The cell constant $F$ for all types of cylindrical resonant cells is proportional to $L^{1/2}/R$. Due to their larger diameters resonances in the radial or azimuthal acoustic mode have high $Q$ values and high resonance frequencies but low $F$ values. A longitudinally excited resonator will have a low $Q$ value but, due to its small diameter, a high $F$ value.

In order to obtain an optimum signal-to-noise ratio, noise control and interfering signals have to be taken into account. Theoretically, the lowest acoustical noise results from random density fluctuations, i.e. Brownian motion, in the gas which is distributed over all frequencies in the sound spectrum. The total power of these density fluctuations is constant, but the frequency distribution is dependent upon local resonances and their $Q$ values. Therefore, using a resonant cell the signal-to-noise ratio will not be improved by considering only these random thermal noise fluctuations.

However, these noise levels are far below other noise sources such as amplifier noise and acoustic disturbances from outside the cell. The power of the amplifier noise varies as $1/f$, where $f$ is the modulation frequency of the light beam. Therefore, in contrast to Brownian noise, it is more advantageous to operate at a cell resonance to increase the generated acoustical signal above the $1/f$ noise level.
noise. A prerequisite is that external acoustic disturbances are shielded from the microphone by a proper cell wall construction, material choice and proper design of inlet and outlet ports.

Noise fluctuations do not have a fixed phase relation with the modulation of the light intensity. Other disturbing factors limiting the sensitivity do have a fixed phase relation. Directly generated coherent acoustical background signals, caused by the modulation process (e.g. chopper, current modulation) can be suppressed in the same way as external acoustical disturbances.

Other, more serious interferences are coherent photoacoustic background signals which are caused by absorption of the light beam in the window material or light scattered or reflected off the resonator wall. They are generated at the same frequency and in-phase with the modulated light beam. In resonant cells, window absorption signals can be suppressed by using large buffer volumes and $\lambda/4$-tubes next to the windows. These one-end-open tubes (Figure 4), placed near the window, act as a notch filter for the window signal at the resonance frequency. The influence of the scattered light on the photoacoustic background signal can be minimized by using, for the resonator wall, a highly reflective polished material, with a thermally well conducting material as substrate, e.g. in the case of the CO$_2$ laser, a polished gold coated copper tube.

In the past special designs have been developed for longitudinally, azimuthally and radially resonant photoacoustic cells, even without windows to improve sensitivity.

In order to improve the selectivity the combination of the Stark effect or Zeeman effect with photoacoustic detection represents an interesting solution for specific molecules such as ammonia (NH$_3$) and nitric oxide (NO). The change in absorption at a specific laser frequency depends on the shift and splitting of the molecular absorption lines of the species under investigation. Although the method does not suffer from interference problems within multicomponent gas mixtures, there are some limitations. The detection is limited to molecules with a permanent electric or magnetic dipole moment; in addition, the shift or splitting of the lines should be observable within the pressure broadened Lorentzian profile at the overlap with the laser frequency. For ammonia at the 10RS transition of the $^{13}$CO$_2$ laser these requirements are satisfied; Thöny and Sigrist showed that the absorption cross-section changed by a factor of two at atmospheric pressure by applying an electric field of 16.7 kV cm$^{-1}$.

Another way to improve the sensitivity for a specific gas is by temperature change. By increasing the temperature the vapor pressure of, for example, an oil with low vapor pressure is increased thereby improving the sensitivity. An elegant cell has been designed by Jalink and Bicanic, who combined a heatpipe and a photoacoustic cell thereby keeping the microphone and windows at room temperature. In addition, a Helmholtz resonant photoacoustic cell (Figure 5) has been developed by Kästle and Sigrist for quantitative temperature-dependent absorption measurements of fatty acid vapors. Helmholtz resonances ($w_{11}$) can be constructed

**Figure 4** Resonant photoacoustic cell. 1, resonator; 2, buffer volume (maximum diameter 40 mm, length 50 mm); 3, buffer ring to decrease buffer radius; 4, ZnSe Brewster window; 5, adjustable $\lambda/4$ notch filter to suppress window signal; 6, inlet gas flow; 7, $\lambda/2$ notch filter to suppress flow noise; 8, outlet gas flow; 9, Knowless microphone.
using a relatively large closed volume \( V \) connected to the outer world via a relatively long narrow duct (length \( L \), cross-section \( S \) at a sound velocity \( c \)) Equation (5):\(^{(24)}\)

\[
w_{H} = \frac{c^2S}{LV}
\]  

Amplification of sound waves can also be achieved with the thermoacoustic effect. The operating principle of such an amplifier connected to a photoacoustic resonator can be explained as follows. The gas inside the acoustical resonator is irradiated by an amplitude modulated laser beam. Trace gas absorption inside the resonator tube will produce a standing acoustical wave; this is the acoustic effect. The amplifier consists of a temperature gradient over a stack of thin sheets separated by a distance equal to two times the thermal boundary layer of the gas (Figure 6). If the gas is moving up and down over the temperature gradient inside the stack, heat energy is transferred to the gas and subsequently into the acoustic standing wave. With such a cell, \( Q \) values have been improved by a factor of 20–30.\(^{(38)}\)

By adjusting the amplifier just below the onset of self-oscillation, the acoustical wave in the resonator will put the amplifier in sustained oscillation, leading to a considerable enhancement of the photoacoustic signal. Noise, acoustic and photoacoustic background signals will also be enhanced. However, with careful design of the cell these levels can be suppressed thereby improving the signal-to-noise ratio.

3.3 Limitations, Selectivity, Interference, Detection Limits

Amplifying photoacoustic signals in resonant cells, reducing noise, using high laser powers, and so on are all used to gain an as high as possible sensitivity for molecular gas absorption. The sensitivity to trace a specific compound depends strongly on its spectroscopic properties. For example, closely spaced rotational absorption lines within a \( Q \) branch of a strong vibrational transition help to reach low detection limits of such a gas. One good example is the \( Q \) branch of the \( v_7 \) band of \( \text{C}_2\text{H}_4 \) in the 10\( \mu \text{m} \) region. The 10P14 CO\(_2\) laser line is in exact resonance with this \( Q \) branch. This results in an extremely low detection limit for \( \text{C}_2\text{H}_4 \) of 6 parts per trillion (1 ppt \( = 1 \times 10^{12} \)) in nitrogen. Some gases can be detected even better (e.g. SF\(_6\)) while others have higher limits due to less coincidence between available laser frequencies and molecular absorption features. In the future this problem may be overcome by powerful tunable infrared lasers such as the PPLN OPO\(^{(39)}\) and quantum cascade lasers.\(^{(40)}\) For detection limits see Table 1 and references therein.

Reactive gases such as ozone are very difficult to quantify in absolute concentrations, although ozone has a very strong absorption cross-section in the CO\(_2\) laser wavelength region, resulting in sub-parts per billion detection limits. Ozone is highly reactive, thus interactions with tubing walls, sampling cuvettes, and the photoacoustic cell, cause rapidly decreasing ozone concentrations. This loss in concentration must be determined over the complete sampling system by calibrating the system with a specific ozone analyzer and checked for linearity over a large concentration range. For example, the breakdown of ozone over a 2-m sampling tube may be as high as 60%\(^{,(67)}\). The degradation of ozone in a photoacoustic cell is determined to be 75% by inserting a second identical photoacoustic cell in the flow system. In spite of these limitations, successful studies have been performed to quantify atmospheric ozone concentrations\(^{(68)}\).

The first excited vibrational mode of N\(_2\) has a long vibrational lifetime (\( \approx 1 \) ms at 1 atm (1 atm = 101.325 kPa) at \( v_1 = 2200 \text{ cm}^{-1} \)). Using kilohertz modulation of the laser beam a phase shift may occur in the generated photoacoustic signal. A well known example is the kinetic cooling effect of CO\(_2\) at CO\(_2\) laser wavelengths (9–11\( \mu \text{m} \))\(^{(54,69,70)}\). CO\(_2\) has a hot-band absorption in this wavelength region and is excited to the \( v_3 \) vibrational level which is almost resonant with the first vibrational level of N\(_2\). Therefore, under atmospheric conditions the energy absorbed by CO\(_2\) will only slowly be converted into a temperature and pressure increase of the gas.

N\(_2\) is not unique. Another example is given in Figure 7 where CH\(_4\) absorbs the CO laser radiation in
Figure 6. Expanded view of the thermoacoustic stack, dimensions are in millimeters. The tunable piston can slide in the upper part of the column which is cylindrically shaped (diameter 23 mm). The lower part (length 20 mm, square cross-section 23 × 23 mm) forms the connection to the stack. This part is heated by Inconel wire. The exploded view of the stack shows the stainless steel plates with the temperature gradient and copper plates to maintain the gradient; stainless steel spacers separate the plates. At the connection between thermoacoustic stack and the photoacoustic resonator, a water cooler removes the excess heat and keeps the lower end of the stack at constant temperature. \(^a\) Unless indicated otherwise, detection limits are reported for single-component mixtures with N\(_2\) at 1 atmosphere as buffer gas. Data are given in ppb (1 part per billion volume = \(1 \times 10^9\)). In a number of references only absorption strengths are given: \(\sigma\) (in \(\text{cm}^{-1}\)) or \(\sigma\) (in \(\text{atm}^{-1}\) \(\text{cm}^{-1}\)), with \(\sigma = N_{\text{tot}} \cdot \sigma\) \((N_{\text{tot}} = 2.5 \times 10^{19} \text{ molecules cm}^{-3}\) at 1013 hPa and 20°C). When the detection system has a sensitivity of typically \(a_{\text{min}} = 1 \times 10^{-9}\), the minimum detectable gas concentration can be calculated from \(c_{\text{min}} = a_{\text{min}}/(\sigma \cdot N_{\text{tot}})\).

\(^b\) At \(^{13}\)CO\(_2\) laser lines.

\(^c\) Multicomponent study.

Figure 7 Vibrational energy transfer due to near-resonant energy levels and a slow V–T relaxation process, in comparison with the modulation frequency (1010 Hz), may lead to an amplitude decrease and phase shift of the photoacoustic signal. This effect can, for instance, be observed when comparing mixtures of methane in nitrogen and in air, due to rapid vibrational energy transfer between methane and oxygen (see text for details).

The \(v_4\) vibrational mode centered around 1306.2 \(\text{cm}^{-1}\). This is the lowest vibrational mode of the molecule; the collisional relaxation lifetime is therefore large compared with the lifetime of other molecules with a smaller energy gap between their lowest vibrational modes and the ground state. The adjacent \(v_2\) mode (1533.3 \(\text{cm}^{-1}\)) becomes thermally populated too (rate constant 13 \(\mu\)s\(^{-1}\) \(\text{atm}^{-1}\)).\(^{71}\) Oxygen has a near resonant vibrational level (1554 \(\text{cm}^{-1}\)) and only 170 collisions are needed to transfer energy to the vibrational mode of O\(_2\) (rate constant \(\approx 28 \mu\)s\(^{-1}\) \(\text{atm}^{-1}\)).\(^{72}\) Since this is a rather fast process most energy is deposited into O\(_2\) and then relaxes slowly to the ground vibrational state; the average number of collisions required for relaxation to the ground state is \(8.3 \times 10^8\) in pure O\(_2\) (at standard temperature and pressure 5 \(\times 10^9\) collisions per second take place). The much larger number density of O\(_2\) compared with CH\(_4\) creates a buffer of vibrational energy leading to an effective transient cooling of the translational degrees of freedom. Due to our high modulation frequency (1010 Hz), we observed this transient cooling by O\(_2\) as an amplitude decrease and a phase change relative to the signal caused by the same amount of CH\(_4\) in N\(_2\).

For specific molecules (such as NH\(_3\), NO) spectroscopic interference can be avoided by combining the photoacoustic effect with the Stark or Zeeman effect; the selectivity is enhanced by intermodulating chopped and electric or magnetic fields. A more generally applicable method is to separate gases, either by gas chromatographic methods, selective trapping inside a cold trap,\(^{26}\) or by a specific chemical reaction (e.g., CO\(_2\) by KOH \(\rightarrow\) K\(_2\)CO\(_3\) and water). In most cases, a small amount of the interfering compound remains present. To take this into account, a multicomponent analysis is necessary selecting a number of laser lines on which interfering species and the species of interest have both strong and weak absorptions.

For a multicomponent analysis of a gas mixture, the laser is subsequently tuned to \(L\) laser lines. For the analysis it is preferable to obtain an overdetermined system, \(G < L\) with \(G\) being the number of gases; in this way, more information can be obtained from the gas mixture resulting in more accurate results.\(^{60,73}\) For practical convenience the background signal generated by window absorption and/or resonator wall absorption is added as a fictive gas component. In the ideal case the measured spectrum is equal to the calculated spectrum. If the absorption coefficient \(I_l\) of a gas \(g\) at laser line \(l\) is known, the total absorption at a laser line, \(a_l\) is given by Equation (6)

\[
a_l = \sum_{g=1}^{G} \Sigma_{l_g} \cdot c_g
\]

with \(c_g\) the concentration of component \(g\). In matrix notation one writes Equation (7)

\[
\vec{a} = \tilde{\Sigma} \cdot \vec{c}
\]
If no measurement errors are specified in the absorption coefficient matrix $\hat{\Sigma}$ and the measured spectrum $(\check{a}_i)$, the gas concentration $\check{c}$ can be calculated by:

$$\check{c} = (\Psi^\top \cdot \Psi)^{-1} \cdot \Psi^\top \cdot \check{a}$$

(8)

where $\Psi^\top$ is the transposed matrix of $\Psi_{\eta i}$, $\Psi_{\eta i} = \eta / a_i$ and $1_i = 1$

4 ENVIRONMENTAL APPLICATIONS

4.1 Stack Gas Emission

Several attempts have been made to measure stack gas emissions from power plants. Due to the high amount of nitrogen oxide (NO and NO$_2$) containing compounds in the emissions, they contribute significantly to photochemical smog formation and acidification of the soil. To reduce the total amount of NO$_x$ in the stack gas, NH$_3$ is added in the exhaust gas towards the chimney. Using a voluminous catalyst, NO$_2$ reduction within the stack gas takes place. In order to check the performance and to avoid an excess of ammonia injection, the ammonia concentration in the chimney is determined. Olafsson et al. have successfully applied a CO$_2$ laser-based detection system for in-situ monitoring of ammonia concentrations.$^{[74]}$ Due to the difficult hostile environment halfway up the chimney (vibrations, temperature fluctuations, etc.), concessions have to be made as to the sensitivity of the apparatus. With a nonresonant photoacoustic cell at 125°C, a detection limit of 1 ppm NH$_3$ was achieved in a multicomponent gas mixture containing 10–15% CO$_2$.

Gas detection using pulsed lasers in combination with photoacoustic spectroscopy in the UV (ultraviolet) and visible has been developed by Stenberg et al. to analyze gas concentrations in fluidized beds and other combustion environments.$^{[75]}$ The probe has been calibrated for typical combustion gases such as N$_2$O, NO, NO$_2$, NH$_3$, SO$_2$ and H$_2$S at temperatures between 20 and 910°C.

Another example of the potential of the photoacoustic systems to control industrial processes is given by Sigrist$^{[22]}$ who was able to follow the ethanol and methanol emissions from a pharmaceutical production plant with a CO$_2$ laser-based set-up with a time resolution of 5 min. With this time resolution, strong concentration fluctuations were observed in the exhaust emission, whereas the gas chromatographic system which was used for comparison proved inadequate.

4.2 Car Exhaust Emissions

CO and CO$_2$ lasers were used to analyze the air polluting emissions from car exhausts. A thorough study was performed by Bernegger and Sigrist to unravel car exhaust mixtures quantifying CO$_2$, NO and 12 hydrocarbons (see Table 2).$^{[76]}$ To this end, absorption cross-sections of the individual species at each laser line were measured; certified trace gas mixtures in a buffer (mostly N$_2$) or other certified methods were used to quantify the absolute values. Once the absorption cross-sections are determined, care has to taken to avoid saturation effects (i.e. nonlinearity of the photoacoustic effect with the laser power$^{[52]}$) and phase shift effects (see previous section). From the absorption cross-sections detection limits can be obtained. In the literature, extremely low detection limits are mentioned based on a signal-to-noise-ratio of one ($S/N = 1$, see Table 1), extrapolated from larger quantities of trace gases in a buffer gas. In reality the detection limits are higher due to multicomponent gas mixtures which induce cross-sensitivities in the absorption coefficients. This mathematical analysis of the photoacoustic spectra is based on the weighted least squares fit of the measured spectra with iteration steps. By choosing the best set of laser lines the error in the calculated concentrations can be reduced.$^{[50,77]}

Car exhaust gas mixtures have been investigated by collecting exhaust samples from different motorcycles, diesel and gasoline engines equipped with catalytic converter. The photoacoustic measurements were compared with conventional gas analytical methods. The engine exhaust stream was mixed with air and a fraction of the mixture was collected in a Tedlar sampling bag. Due to the strong water vapor absorption at the CO laser wavelengths and the high water vapor concentrations of 1–2% in the sampling bag, the gas was flowed over a dry-ice cold trap before analysis thereby reducing the water vapor concentration to 0.1%.$^{[76]}

4.3 Ambient Air Monitoring

Examples of laboratory photoacoustic studies on multicomponent studies can be found elsewhere.$^{[22]}$ Here we mention two examples of mobile systems which were developed and used in field campaigns. A complete laser photoacoustic system which fitted into two medium sized boxes (0.3 m$^3$ each) was developed by Rooth et al. to detect ammonia gradients above the heath in the Netherlands.$^{[54]}$ The potential danger of nitrification by NH$_3$ of such nutrition poor areas motivated the measuring campaign to follow the deposition/emission ratio of ammonia over the area. The system operated for several months, taking data for water vapor, CO$_2$ (every 40 min) and ammonia (every 6 min).

Another system was developed by Sigrist et al. Installing the whole set-up in a small trailer the stress on the equipment is less severe. Thanks to this approach the system has been operational for years and has been

* All data are given in parts per million (ppm) with their uncertainty, except for CO₂ (which is in %). The effect of drying of the gas could be observed.
applied in several field campaigns in urban and rural environments. For example, multicomponent gas mixtures were analyzed during sunny days in the summer, using nine laser lines, for the concentration of \( \text{H}_2\text{O}, \text{CO}_2, \text{NH}_3, \text{O}_3 \) and \( \text{C}_2\text{H}_4 \) with a 5 min time resolution.

5 BIOLOGICAL AND MEDICAL APPLICATIONS

5.1 Postharvest Physiology

To delay the effects of aging and ripening, many harvested crops are stored under reduced oxygen concentrations thereby lowering the respiration rate and the rate at which metabolic processes take place. However, when the oxygen concentration falls below a certain limit, crops switch to fermentation, an alternative method to generate the energy needed to sustain their vital functions. This anaerobic metabolism, converts glucose, via several intermediate steps, into acetaldehyde which is then quickly reduced to ethanol. As accumulation of these products in the tissue may affect the quality of the crop, it is necessary to control the rate of fermentation during storage. The concentrations of the volatile in the headspace is an accurate quantitative indicator to assess the rate of fermentation.

Another gas of interest during crop storage is the plant hormone ethylene, which is mainly emitted during ripening of climacteric fruits, i.e. fruits which show a sudden rise in respiratory rate just prior to full ripening. Furthermore, carbon dioxide may be analyzed to assess both respiration and fermentation rates and ethane may be analyzed as the end product of lipid peroxidation causing breakdown of cell membranes.

The noninvasive nature of the photoacoustic trace detection technique renders it extremely suitable for applications in the field of postharvest physiology. Moreover, the high sensitivity combined with fast analysis allows study of an individual piece of fruit so that metabolic activity may be followed in real time. Here we give an overview of some recently performed experiments on single pieces of harvested crops. In general, the crop is placed in a glass container which is connected to the flow-through system leading the released metabolites to the photoacoustic cells. Storage conditions are simulated by supplying the sample with a premixed flow of oxygen and nitrogen (Figure 8); the storage temperature is controlled using a refrigerator.

![Figure 8](image-url) Laser photoacoustic detection set-up. 1, 2 and 3, trace gas flows; 4, triple photoacoustic cell; 5, liquid nitrogen cooled CO laser; 6, grating to select the appropriate transition; 7, chopper; 8, catalyst to remove hydrocarbons from the flow toward the fruit; 9, KOH scrubber to remove CO\(_2\); 10, switching valve for (an)aerobic conditions; 11, cuvettes, one containing a tomato, the other empty as reference; 12, switching valve to select cuvette; 13, cold trap to freeze out interfering gases selectively.
The ethylene emission of climacteric fruit shows a distinct rise during ripening, reaching a maximum when the sample is at its best; subsequent degradation of the product accompanies a decline in the ethylene release. To localize the ethylene release of different crops, De Vries et al. applied the extreme sensitivity of CO₂-laser based photothermal and photoacoustic detectors. Larger differences in emission pathways were found ranging from more than 99% through the skin for banana, apple and citrus fruits, to around 85% through the pedicel “stem” for tomato and bell pepper. In addition, the amount of ethylene released varied from a few tenths to a few thousands of nanoliters per hour per fruit.

When stored crops are returned from controlled atmosphere (CA, low oxygen, high CO₂, low temperature) conditions to normal atmospheric conditions, a rapid peak in the acetaldehyde release occurs due to oxidation of the ethanol accumulated in the tissue. This process was followed in real time for red bell peppers by Zuckermann et al. using a CO laser-based photoacoustic detector. Returning a pepper from anaerobic conditions to normal oxygen conditions (21%) caused a peak in the acetaldehyde release with a maximum of about four times the anaerobic level occurring within 25 min after the switch. The high velocity with which the process takes place caused the authors to conclude that the effect is mainly due to the peroxidative action of the enzyme catalase. Further investigations have shown that the acetaldehyde peak occurs even at much lower postanaerobic O₂ concentrations with roughly equal intensity, though not as fast (Figure 9).

During CA storage of apples it is common practice to apply low concentrations of carbon dioxide externally as it is known to inhibit respiration. As both respiration and fermentation produce carbon dioxide, it is difficult to predict a priori how the fine balance that exists between respiration and fermentation at low O₂ concentrations, will be affected. For pears, at oxygen levels around 1% a substantial rise in the acetaldehyde release could be observed upon addition of a few percent of CO₂. The crop is no longer able to retrieve its energy from respiration and is forced to generate additional energy through fermentation.

5.2 Plant Physiology

One of the major environmental factors influencing crop productivity is flooding. Tolerant species often possess
“escape” mechanisms such as fast underwater growth that minimizes the duration of total submergence.\(^{83}\) However, at early vegetative stages, even in “deep-water” types of rice, such escape is precluded by a lack of sufficiently vigorous shoot elongation for resurfacing. Survival of submergence under these circumstances depends on intrinsic physiological and biochemical tolerance. Screening of cultivars is needed by plant breeders, agrotechnology and biotechnology to achieve sustainable improvements in productivity of rice farming in the rainfed lowland of southeast Asia.\(^{84}\) Submergence is not an easily quantified stress compared with, for example, cold, heat, or pollution, since it cannot be assessed by one simple analysis. This is because it involves exclusion and entrapment of several key gases and interference with illumination. Normal rates of respiration and photosynthesis are affected; differences in submergence tolerance are also reflected in a different reaction to low oxygen concentrations. Precise measurements of fermentation rates can result in a powerful tool to shed some light on submergence stress. As mentioned in the previous chapter anaerobic fermentation in plant tissue can be studied by use of photoacoustic techniques, through detection of ethanol, acetaldehyde and CO\(_2\) by means of a liquid nitrogen cooled CO laser. Experiments in the laboratory show that seed and seedlings of rice species with different degrees of tolerance toward submergence possess different fermentation rates under anaerobic conditions. Figure 10 shows that after a period of 5 h in which both species have similar ethanol production rates, the most tolerant species (FR13A) starts to slow down fermentation. After about 20h the production rate for the less tolerant species (CT6241) is doubled with respect to the other; it probably runs out of storage material much faster than the resistant one.

Besides fermentation, the availability of oxygen in the roots is of major concern for the plant. In case of partial or complete submergence, rice plants must rely on a well-developed system for gas transport through the plant. The real path of the gas (especially in the shoots) and how this changes with long periods of submergence is unknown. Photoacoustic trace gas detection can also be very useful in this case: a known amount of the tracer gas SF\(_6\) (biologically inactive; atmospheric lifetime 3200 years) is injected into the nutrient solution around the roots and detected coming out of the tip of the leaves, while the rest of the plant is completely submerged in water. We use SF\(_6\) as the tracer gas because the CO\(_2\) laser photoacoustic system is particularly sensitive to this gas (down to parts per trillion level). Figure 11 represents a typical output from the tip of a leaf (enclosed in a cap) after the injection of 4.5 mL of H\(_2\)O saturated with SF\(_6\). The plant is kept under water during the experiment.

A question we can readily answer with our system is what kind of gas transport is predominant in the shoots of a young rice seedling. It could be either through aerenchyma (i.e. intercellular spaces present in roots) or through the air layer that is wrapped around the hydrophobic surface of the leaves. This air layer is destroyed by dissolving a few drops of detergent in the water surrounding the plant; because the SF\(_6\) signal dropped to zero immediately afterwards, we can exclude the presence of aerenchyma in the shoots of the seedling.

**Figure 10** Production rate of ethanol plotted against time for rice seeds during germination under anaerobic conditions. The flooding resistant species (FR13A)[●] does not ferment as much as the intolerant species (CT6241)[○] indicating that it preserves its energy for the postanaerobic period.

**Figure 11** Depletion of the air layer around the submerged rice leaves by addition of detergent. The effect was monitored by SF\(_6\) diffusion which was added into the root compartment (physically separated from the shoot compartment). SF\(_6\) was collected from a small cap filled with air around the tip of a leaf. The air layer is completely restored by replacing the detergent with clean water. During the whole experiment the plant was kept completely submerged.
Another example of trace gas detection within plant physiology is the intriguing question of whether ethylene is a reaction to the growth of the pollen tube inside the pistil (i.e. a form of wounding) or if the pollen tube growth is a consequence of the hormone production by the flower (i.e. a real signal for the plant). It is known that a pollinated flower emits ethylene at the parts per billion level, with a characteristic double peak shaped curve.\(^{(85)}\)

To answer this question, incongruous pollination has been performed on tobacco flower \((\text{Nicotiana tabacum})\), i.e. by pollinating the flower with pollen from other species that show a certain degree of compatibility with the tobacco plant. For this we used pollen with a very low compatibility to the tobacco flower \(\text{Nicotiana repanda}\); it enters the stigma and stops immediately thereafter. The production of ethylene, detected by photoacoustic spectroscopy, in these cases is very different, as shown in the Figure 12.

The first peak is always reproduced in both height and time, and, comparing these results with microscopy work,\(^{(86)}\) it corresponds to the entrance of the pollen tube in the stigma. The second peak has a more complicated shape which is never perfectly reproduced with incongruous pollination and which does not simply follow the growth of the pollen tube in the pistil. This might indicate that the second peak is a specific signal from the plant and not a simple wounding effect.

### 5.3 Microbiology

Biological systems cannot always use molecular nitrogen for their metabolic processes. To this end, dinitrogen \((\text{N}_2)\) must be reduced, i.e. the triple bond must be broken to convert the molecule into more appropriate compounds such as ammonium \((\text{NH}_4^+)\), nitrate \((\text{NO}_3^-)\) or amino acids. Only few organisms are capable of reducing dinitrogen; among them are the diazotrophic cyanobacteria.\(^{(87)}\)

The nitrogen fixation process is induced by the enzyme nitrogenase, which is very sensitive at low oxygen concentrations. However, like other organisms, cyanobacteria need energy which they derive from photosynthetically produced oxygen. In order to activate both photosynthesis and nitrogen fixation, these processes are separated either in time or in place.\(^{(88,89)}\) \(\text{Nodularia spumigena}\) belong to the last category. They consist of large strings of cells formed mainly by vegetative cells in which photosynthesis takes place alternated every 10 to 20 cells by one heterocyst in which the nitrogen fixation takes place.\(^{(90)}\)

The acetylene \((\text{C}_2\text{H}_2)\) reduction method is commonly used to follow the process of nitrogen fixation.\(^{(91)}\) As for \(\text{N}_2\), the triple bond of acetylene is broken and reduced to ethylene \((\text{C}_2\text{H}_4)\)\(^{(92)}\) which can be detected very sensitively with laser photoacoustics.\(^{(52)}\)

In the past, gas chromatography utilizing flame ionization detection and photon ionization detection were applied to investigate the nitrogen fixation process.\(^{(91,93)}\) Long incubation times, up to several hours, are necessary to reach gas concentrations observable for the equipment making dynamic measurements unfeasible.

Laser photoacoustic experiments have been performed to study the dynamic behavior of nitrogen fixation.\(^{(94)}\)

To avoid the buffering volume of the water, the algae \(\text{Nodularia spumigena}\) were put on filter paper and a gas mixture of \(\text{O}_2\) and \(\text{N}_2\) with different concentrations of acetylene was flushed over the sample. In this way the effect of parameters such as light intensity and temperature could be studied with a 20 s time resolution.

Utilizing the \(\text{CO}_2\) laser as radiation source instead of the \(\text{CO}_2\) laser in the photoacoustic spectrometer, it is possible to detect other interesting gases. Methane and dimethyl sulfide emission in rice field paddies forms an important threat to the environment. Methane is, after \(\text{CO}_2\), the second most efficient greenhouse gas whose biological production from the man-made rice cultures, needs further clarification.\(^{(95,96)}\) Dimethyl sulfide is a climate-active natural marine emitter and responsible for sulfur transport into the atmosphere. The fact that both gases can be detected very efficiently by photoacoustic techniques, at the water surface as well as at various water depths, forms an important challenge for future activities at field sites.

### 5.4 Human Health, Noninvasive Breath Analysis

Since ancient times it has been known that the smell of exhaled air can be used as an indicator of several processes
taking place in the human body;\(^{97,98}\) uncontrolled diabetes produces a sweet fruity odor, advanced liver diseases entail a musty fishy reek, failing kidneys bring about a urine-like smell and a lung abscess can be brought to light by its putrid stench. In the past, several attempts to use trace gas detection of exhaled air have been performed with variable success because of the nonsufficient detection limits of the detectors available. Gases produced in the body are transported to the lungs and are diluted (at rest, healthy persons exhale approximately 1000 L h\(^{-1}\)) before being exhaled. To measure them, it is necessary to enrich the air samples by adsorbing the gases on an agent and releasing the concentrated gas at a certain moment rendering the measurements less accurate and difficult to reproduce.\(^{99}\)

Measurements on the effects of UV radiation on the human skin are presented to illustrate the possibilities of photoacoustic trace detection in this field. In these experiments lipid peroxidation of the skin is monitored.\(^{100}\) UV radiation causes reactive oxygen species to be formed in the skin.\(^{101}\) These radicals can damage the lipids in the cell membranes producing small hydrocarbons such as ethane, pentane and ethylene.\(^{102}\) With the CO\(_2\) laser set-up it is advantageous to study these latter molecules.\(^{21,52}\)

A small amount of air is sampled from the exhaled air and cleaned from CO\(_2\) (typically 5%), water vapor and other spectroscopically interfering gases like acetone and ethanol. The test persons are measured while resting under a solar bench. Under UV radiation a steady increase of the exhaled ethylene is observed with a 2 min time delay (Figure 13). The increase continues until the solarium is switched off after 15 min (the maximum exposure time advised). During the subsequent decrease of ethylene emission two decays can be distinguished; a fast and a slow decay. The first decay is caused by the washout of ethylene from the blood; the second decay results from ethylene stored in the body tissue. The dynamics of the system, i.e. transport of gases through the body, yields information for pharmakinetic research. In order to determine the locally induced damage, a specially designed cell was placed on the skin. Immediately after the start of the UV exposure a steady and constant production of ethylene in the skin was observed. Combining the two results, it is concluded that the slow increase in ethylene signal in the exhaled air is caused by the buffering effect of the human body.

Apart from the effect of UV radiation on the skin, other effects induced by lipid peroxidation can be studied: patients suffering from chronic obstructive pulmonary disease have increased cell membrane damage in the lungs; patients with pancreas problems cannot digest long-chain fatty acids, resulting in a lack of ethylene in the exhaled air after consumption of these fatty acids; patients suffering from cardiac insufficiency have increased ethylene levels in the exhaled air.

**5.5 Entomology**

Methane has been recognized as one of the principal greenhouse gases, second only to CO\(_2\). Its estimated contribution to the enhanced greenhouse effect varies between 15–20\% (Intergovernmental Panel on Climate Change, 1990) depending on the time window for which the calculation is made. Methane is not only a potent greenhouse gas, it is also chemically active in the atmosphere thus influencing concentrations of several important species, e.g. OH, O\(_3\) and CO. Biogenic sources are responsible for the major part of the global methane flux (70\%).\(^{103}\) Some arthropods (i.e. millipedes, cockroaches, termites and scarab beetles)
ENVIRONMENT: TRACE GAS MONITORING

Figure 14 Methane release together with the CO₂ emission, during a complete respiration sequence of breathing (starting at 5.15 h and 6.08 h) and constriction (starting at 5.48 h and 6.32 h) for the cockroach species Gromphadorhina portentosa.

are believed to contribute up to 25% of the total budget.¹⁰⁴

Gas chromatography allows measurement of the methane release of single animals only after incubation for several hours. Consequently, these measurements cannot provide information about the dynamic character of the gas emission. Infrared absorption measurements featuring fast response time permitted observation of the dynamics of CO₂ emissions.

Besides CH₄ and CO₂ emissions from insects, water vapor release has been the subject of many studies. Information about water loss dynamics in insects is based upon theoretical modeling, sensitive weighing and relatively slow direct water vapor measurements.¹⁰⁵–¹⁰⁸ With laser photoacoustic detection Bijnen et al. showed that cockroaches at rest show a regular breathing pattern that optimizes oxygen uptake and reduces water loss.²⁰ Respiration patterns of cockroaches and beetles have been recorded where microbiologically produced methane was found to be co-emitted with CO₂ and water vapor (Figure 14). This on-line observation is to be utilized in a study to establish conditions for hyperventilation of insects so that the minimum amount of insecticide will suffice to kill noxious insects which, for example, are known to transmit viral diseases.

6 COMPARISON WITH OTHER SPECTROSCOPIC METHODS IN TRACE GAS MONITORING

Fast and sensitive trace gas detection is not exclusively reserved for photoacoustics. In general, all spectroscopic techniques are able to monitor gas absorptions on a subsecond timescale. However, depending on the type of application not all techniques possess a high sensitivity.

Air pollution can be very well studied with long-path light absorption techniques rendering low detection limits; the sensitivity of the method relies strongly on the path length. A broadband light source (often UV) is directed towards a receiver over an open path in the atmosphere.²² For stratospheric studies the sun has
also been used as a light source applying a 0.01 cm\(^{-1}\) resolution Fourier transform spectrometer on board the space shuttle as part of the Spacelab 3 mission.\(^{109}\) Laser-based long-path absorption techniques are used either with multipass arrangements, LIDAR (light detection and ranging) or the related DIAL (differential absorption lidar) methods.\(^{22}\) In contrast to CW operation, using pulsed lasers has the advantage that the backscattered light gives spatial information about the atmospheric absorption pattern.\(^{110}\)

All methods described above derive their sensitivity from long-path absorption thereby integrating over hundreds of meters. Laser-based photoacoustic detection has the advantage of tracing gases locally and can therefore also be used in laboratory studies. Other laser-based techniques which can also achieve a high sensitivity within a small volume of gas are intracavity laser absorption spectroscopy, which relies on very long effective absorption length within a high optical Q factor laser cavity;\(^{111}\) cavity ring down spectroscopy combines very accurate decay time measurements of light pulses and a high Q optical cavity resulting in long effective absorption lengths.\(^{112}\) In comparison with these techniques laser photoacoustics has the advantage that it is background free: it does not rely on a decrease of the transmitted light but on an increase from the zero baseline, i.e. on a collisional release of energy after absorption.

Other background-free and therefore strongly competitive techniques are laser-induced fluorescence (LIF) and multiphoton ionization (MPI). These techniques are both extremely sensitive due to the high collection efficiency of photomultipliers and ion counters; both can be applied locally within a small gas volume. LIF and laser photoacoustics are complementary in energy release. The advantage of LIF is that it can also detect free radicals (e.g. OH) with relatively low laser powers. MPI can be very selective and sensitive for molecules with a higher mass. An elegant example is the detection of OH with LIF in the upper atmospheric layers with an aircraft, avoiding spectroscopic cross interferences from other molecules, laser-induced generation of OH, depletion of OH during sampling, etc.\(^{113}\) A restriction of LIF is the lifetime of the excited levels. As stated in the introduction, the competition between collisional relaxation and radiative decay restricts LIF mainly to the visible and the UV part of the electromagnetic spectrum.

ACKNOWLEDGMENTS

The authors wish to thank D.H. Parker and J. Reuss for their helpful discussions and continuous support. We are also grateful to H. Zuckermann (Open University of Israel), H.S.M. de Vries, J. Oosterhaven and R.H. Veltman (ATO-DLO) for their collaborations in postharvest research; M.B. Jackson (University of Bristol, UK) for his indispensable contribution to the rice plant research; C. Mariani (University of Nijmegen), D. de Martinis (ENEA, Italy) for their polination research; M. Staal, L. Stal (NIOO) for their contributions in the field of microbiology; R. Berkelmans, K. Kuiper, P. Hollander (Free University, Amsterdam), P. Scheepers, R. Dekhuijzen (University of Nijmegen) for their help in breath analysis; and P. Kestler (University of Osnabrück, Germany) and J. Hackstein (University of Nijmegen) for their collaborations on entomological applications. Furthermore we thank F. Bijnen, S. Persijn, T. Groot, E. Santosa for their experimental support and C. Sikkens, C. Timmer, H. Schoutissen and L. Gerritsen for technical assistance. Finally we would like to thank the Dutch Technology Foundation (contracts no: NNS44.3404, NNS.4596 and NNS55.3921), the Dutch Royal Academy of Science (contract 95BTM04) and the European Union (contracts no: BRFSCT-CT91-0739, ERB514-PL95-0708, PL95-0468 and ERB4062-PL970089) for their financial support.

1 INTRODUCTION

Air pollution is an extremely dynamic phenomenon, which makes its understanding and therefore its control difficult. This dynamic behavior appears in physical terms in the diffusion and transport of emitted pollutants and chemically through the many reactions which take place in the atmosphere. It is therefore of outstanding importance to be able to correlate emission and immission, and characterize the impact of different kinds of sources of pollution (industries, vehicles, domestic heaters) on the environment. Currently existing devices, however, although very sensitive, only provide spot measurements at the ground level. 3-D information, reflecting the dynamic character of pollution, has been for a long time sorely lacking.

These considerations have induced the development of the LIDAR technique, and in particular DIAL [also called differential absorption and scattering (DAS)]. These devices indeed allow selective measurements of pollutant concentrations over several kilometers, range-resolved like radio detection and ranging (RADAR), and in an interactive manner (i.e. without the usual need for samples). It becomes then possible to obtain “3-D maps” of concentrations, which show the propagation, spread, and chemical evolution of emitted pollution.

The DIAL technique was demonstrated for the first time in 1966 by Schotland, who evaluated vertical profiles of water vapor contained in the atmosphere. The first mapping experiments were performed in 1974 by Rothe et al. In the 1980s, the performances of the systems were widely extended by several research groups, essentially in Sweden, England, Germany, and the United States.

However, LIDAR systems remained in the laboratory until very recently. The breakthrough to industrialization and standard use by the Environmental Protection Agencies (EPAs) has been allowed by different conjugated progress. First, the capabilities of today’s DIAL systems almost perfectly match the needs and requirements of air enforcement regulations. In particular, LIDAR provides 3-D maps of concentrations of nitrogen oxides, sulfur dioxide, ozone, toluene, and benzene at the highest sensitivity (parts per billion range), over large distances, and tropospheric ozone generation. Industrial applications are also numerous, such as site monitoring, identification of diffuse emissions, and evaluation of the impact of new emitters through plume dispersion studies. The use of LIDAR systems to validate numerical models is also discussed. The last section is dedicated to the calibration of the systems, intercomparison with standard analyzers, and legal aspects in terms of certification and new standards.
this at much higher resolution and lower cost than standard networks. It is also, moreover, able to monitor the time evolution of pollutant concentration distributions, at high temporal resolution (some minutes) or in longer time frames.

Optical techniques are moreover often recognized as delivering more representative data than spot measurements: an integrated value over a defined optical path (ranging from few meters to several hundred meters) always contains more information than precise spot data at a wrong location! These arguments brought standardization commissions to introduce optical techniques into legislation. Pioneering work has been performed in this respect by the German commission Verein Deutscher Ingenieure (VDI)/Deutsche Institut für Normung (DIN).²¹,²³

The most recent and decisive progress is a technological step forward, which makes the new DIAL systems very reliable devices, reaching the highest industrial standards. The advent of new tunable all-solid-state laser systems, such as vibronic lasers²⁰–²² or laser-pumped OPOs²³,²⁴ has opened up a new era in the domain of user-friendly and fully automatic DIAL operation.

“All-solid-state” DIAL systems, based on flashlamp-pumped Ti:sapphire lasers, have recently been very successful.²¹,²⁵,²⁶ The development of the laser used was fully dedicated to LIDAR applications, in order to reach the specific requirements such as high energy, dual-wavelength operation, extreme reliability, and user-friendliness. The wavelength range accessible by the laser and its extension by non-linear optical devices make it an ideal tool for both DIAL and meteorological applications.

DIAL instruments can be classified in two different categories, depending on the application: stationary and mobile. The stationary systems, such as those installed in Berlin and Leipzig,²⁰ are dedicated to routine 3-D mappings over the city, whereas mobile units are mainly used for campaigns. Numerous campaigns have been performed in large cities such as Zürich,²⁷ Stuttgart, Lyons, Geneva,²⁸ Berlin,²⁹ Athens,³⁰,³¹ Seville,³²,³³ and Mexico.

This article discusses the advantages offered by DIAL/LIDAR instruments in analyzing gaseous and particulate pollutants, examples of application, and norming activities.

### 2 THE DIFFERENTIAL ABSORPTION LIGHT DETECTION AND RANGING TECHNIQUE

When a laser beam is sent into the atmosphere, it is scattered in every direction by particles and molecules present in the air. This scattering is essentially caused by Rayleigh scattering on nitrogen and oxygen molecules and Mie scattering on aerosols (dusts, water droplets, etc.). In a LIDAR arrangement, the backscattered light is collected by a telescope, placed close to the laser emitter (see Figure 1). The signal is focused on to a photodetector through a spectral filter, adapted to the laser wavelength. Since a pulsed laser is used, the intensity of the backscattered light can be recorded as a function of time, which provides spatial resolution. The received signal reflects the aerosol and molecular concentrations as a function of distance, similar to an “optical RADAR”.

More precisely, the received number of photons from a distance \( R \) at a wavelength \( \lambda \) is given by Equation (1) (assuming that each photon is only scattered once):³⁴

\[
M(R, \lambda) = M_0(\lambda) \frac{A_0}{R^2} \beta(R, \lambda) \Delta R \xi(R, \lambda)
\times \exp \left( -2 \int_0^R a(R', \lambda) \, dR' \right)
\]

where \( M_0(\lambda) \) is the number of photons emitted by the laser, \( A_0 \) the area of the receiver telescope, \( \Delta R \) the spatial resolution of the system, essentially limited by the laser pulse duration and the dwell time of the acquisition electronics, \( \xi(R, \lambda) \) the detection efficiency, \( \beta(R, \lambda) \) the volume backscattering coefficient, and \( a(R', \lambda) \) the total atmospheric extinction coefficient.

The detection efficiency \( \xi(R, \lambda) \) takes into account every geometrical and optical factor of the receiver arrangement. \( \xi(R, \lambda) \) can be separated into two different parameters, one dedicated to the spectral characteristics \( \xi(\lambda) \) of the detection channels (filters, monochromator, etc.) and of the sending and receiving optics, and the other, \( \xi(R) \), to geometrical properties such as the overlap between the field illuminated by the laser and the telescope field of view. The latter parameter is often used to somewhat compress the large dynamic range of the signal.³⁵,³⁶
The signal dependence on the aerosol concentration, which allows their detection, is included in two scattering parameters: the volume backscattering coefficient $\beta$ and the extinction $\alpha$. However, the exponential factor $\exp[-\int_{R'}^{R'} \alpha(R', \lambda) \, dR']$ represents the total atmospheric attenuation of the laser beam, via the Beer–Lambert law. The extinction is caused by two different processes: the Rayleigh–Mie scattering $\alpha_{RM}$ and the specific molecular absorption $\alpha_A$ of the different species present in the atmosphere. The extinction coefficient $\alpha_{RM}$, like $\beta$, is an average value of the size distribution, shape, and composition (refractive index) of the aerosols. In order to solve Equation (1), a standard method is to use a fitted value of the $\alpha_{RM}/\beta$ ratio.\(^{(37,38)}\) This provides backscatter ratios as a function of distance, which qualitatively represent the spatial distribution of the atmospheric particle density.

The molecular absorption $\alpha_A$ allows a specific detection of a particular gaseous pollutant, using the DIAL technique. This technique is based on the use of a pair of wavelengths close to each other, with a large absorption coefficient difference (called $\lambda_{on}$ and $\lambda_{off}$, for on-resonance and off-resonance wavelength, respectively).

Let us now assume that such a pair of wavelengths ($\lambda_{on}$, $\lambda_{off}$), chosen for the detection of a pollutant B, is sent into the atmosphere (Figure 1). It is important that $\lambda_{on}$ and $\lambda_{off}$ lie close enough to exhibit the same scattering properties. So, the first plume A in Figure 1 (which does not contain the detected species B) causes an increase of the backscattered signal, because the concentration of aerosols is larger than in the clear atmosphere, but the same amount for both pulses. Conversely, the second plume, which contains a certain quantity of the pollutant, absorbs the backscattered signal at the $\lambda_{on}$ wavelength much more strongly than at the $\lambda_{off}$ wavelength. From this difference, using the Beer–Lambert law, we obtain the specific concentration of the considered pollutant as a function of distance. More precisely, if we take the ratio of the two LIDAR returns (each represented by Equation 1), and then the derivative of its logarithm, we obtain Equation (2):

$$N_A(R) = \frac{1}{2[\sigma(\lambda_{on}) - \sigma(\lambda_{off})]} \frac{d}{dR} \ln \frac{M(R, \lambda_{off})}{M(R, \lambda_{on})}$$

(2)

where $N_A(R)$ is the pollutant number density and $\sigma(\lambda)$ the absorption cross-section at the wavelength $\lambda$. Note that to obtain Equation (2), the detection efficiency $\xi(R, \lambda)$ must be the same for both laser beams, so that a perfect geometric alignment is necessary.\(^{(39)}\) As mentioned before, both wavelengths must be taken close enough so that the backscattering and extinction coefficients are identical, i.e. $\beta(\lambda_{on}) = \beta(\lambda_{off})$ and $\alpha_{RM}(\lambda_{on}) = \alpha_{RM}(\lambda_{off})$.

The pollutant concentration is then measured range resolved. By scanning the measurement direction in azimuth or elevation, two-dimensional (2-D) or 3-D mappings are obtained, like a molecule-specific RADAR.

### 3 DIFFERENTIAL ABSORPTION LIGHT DETECTION AND RANGING SYSTEMS

In the 1980s, ultraviolet differential absorption light detection and ranging (UVDIAL) systems were mainly based on dye lasers, pumped by frequency doubled or tripled Nd:Yag or excimer lasers. The dye laser output was then frequency doubled to reach the 225–400 nm region.\(^{(63)}\) where major pollutants (nitrogen oxides, sulfur dioxide, ozone, etc.) exhibit strong absorption features. The complexity and user unfriendliness of these laser systems definitely prevented the widespread of LIDAR systems at this time.

The advent of high-energy, tunable, all-solid-state lasers in the early 1990s completely changed this situation. DIAL systems were finally considered as reliable “black boxes”, which could be widely used for air pollution monitoring applications. This also induced industrial developments of DIAL systems. The first “all-solid-state” UVDIAL system commercially available, based on a flashlamp-pumped Ti:sapphire laser, was for example presented in 1993.\(^{(41)}\)

Since then, Ti:sapphire-based UVDIAL systems have been very successful. A typical example of such an instrument, manufactured by Elight Laser Systems, is presented below.

The laser is a flashlamp-pumped Ti:sapphire laser in an oscillator/amplifier configuration. A patented oscillator,\(^{(42)}\) based on a dual prismatic dispersion arrangement, provides both reference and probe wavelengths ($\lambda_{on}$ and $\lambda_{off}$), either simultaneously or alternately. The switching is performed by a rotating-face parallel prism allowing collinearity between both laser beams of better than 100 µrad. The use of a single laser drastically reduces maintenance.

Mode quality and frequency stability are assured by a graded reflectivity (super-Gaussian, 50% maximum) output coupler. With a Pockels cell as Q-switch, this laser system delivers 250 mJ in 20 ns pulses with a bandwidth of 0.5 cm\(^{-1}\) over the whole tuning range (720–900 nm).

The high peak power allows efficient nonlinear optical frequency conversion [second harmonic generation (SHG) \~20%, third harmonic generation (THG) \~7% of the fundamental] to reach the ultraviolet (UV) absorption bands of the detected pollutants. The laser beam is expanded 10 \times to meet eye safety requirements (according to VDI/DIN 0837).
Note that for the eye safety reasons mentioned above, some weaker bands of pollutants have to be chosen instead of stronger ones, which lie above 400 nm and lower than 1400 nm. The laser beam is sent into the atmosphere by a dual scanning periscope in composite material which also directs the backscattered light back to the 400 mm/f3 parabolic mirror (Figure 2). This telescope focuses the light on to an iris to limit the field of view to about 0.5 mrad. The signal is detected by a photomultiplier, through a motorized filter wheel, in order to select automatically the proper spectral filter. The signal is digitized by a 12 bit, 40 MHz system, allowing a spatial resolution of 3.75 m in this case (for some emission measurements faster analog-to-digital converters are used). The data are handled by a PC microcomputer which controls every parameter: wavelength setting and calibration, receiver parameters [photomultiplier tube (PMT) high voltage, gain, spectral filter used], and the periscope steering. The software is Windows-based, and includes a sophisticated inversion algorithm optimising the signal-to-noise ratio (S/N), and modules for automatic operation, on-line evaluation of the data, and high-level graphic representation.

The described instrument is moreover of very compact design (110 × 100 × 120 cm), which allows its installation in a small van (e.g. a Mercedes MB 100). It is able to perform 3-D mappings of NO, NO2, SO2, O3, benzene, and toluene at high sensitivity (a few parts per billion) and over large distances (several kilometers). Typical specifications are listed in Table 1.

An additional extension of the accessible wavelength range, in particular in view of hydrocarbon detection, is made by an OPO in a “no-tracking” configuration. The decisive advantage of pumping with a tunable laser such as Ti:sapphire is that no geometrical alignment of the OPO is necessary. The device can even be monolithic with mirror coatings directly applied on the nonlinear crystal facets. With such a device, infrared (IR) radiation from 1 to 4 µm is generated with an efficiency of up to 10% just by tuning the pump wavelength from 730 to 860 nm.

Recently, a new aspect was brought out by Douard et al. concerning multi-DIALs. The idea is to send a broad-band laser (like a free-running OPO) in the atmosphere and to analyze spectrally the backscattered light by an optical multichannel analyzer (OMA) or a Fourier-transform infrared (FTIR) interferometer. This technique was demonstrated for the first time in 1995. The decisive advantage of the method is the capability of detecting several species by DIAL at the same time. A very attractive application is thus the detection of volatile organic compounds (VOCs) in the mid-IR region (3.3–3.5 µm).

It should be noted at this point that taking into account the different sources of noise and error, the sensitivity is actually a value in parts per million times meters, because of the Beer–Lambert law: for a given S/N, the larger the range of integration, the lower the possible detected concentration. For example, if the detection limit is 1 ppm m, the lowest detectable level is 1 ppm for a range resolution ΔR of 1 m (emission conditions), but 5 ppb for a range resolution of 200 m (immission conditions).

The maximum distance of measurement is typically 3 km for standard meteorological conditions. The sensitivity and the absorption path can be increased in a large extent by using topographic targets down to about 500 ppt for a 10 km pathlength. Nevertheless, the spatial resolution is then lost in one direction, and only average 2-D mappings are obtained.

4 EXAMPLES OF THREE-DIMENSIONAL MAPPING OF GASEOUS POLLUTANTS

We present in this section several examples of DIAL measurements of gaseous pollutants. The first part is dedicated to the study of physical atmospheric dynamics, and in particular to transport processes and spread of primary pollutants in different topographic and meteorological conditions.

The first application consists in emission measurements in industrial environments. Figure 3 shows a typical example of a DIAL concentration profile. The detected pollutant is SO2. The measurement was performed directly through the chimney plume of a power plant. This example shows the ultimate spatial resolution of the system, of about 2 m, which allows the observation of the structure of the plume. The two concentration maxima are, indeed, due to the use of two separate burners in the combustion chamber. The measured SO2 values are, furthermore, in good agreement (within ±10%) with the standard spot measurements, performed by the company inside the chimney. Moreover, remote sensing allows the plume concentration to be followed as a function of distance, and thus to characterize the dilution and its expected impact (see section 6).

Scanning the measurement field in azimuth or elevation yield the unique access to tridimensional maps of concentration. Figure 4 represents such a map of the NO2 concentration emitted by a chemical factory. The high spatial resolution allows here to observe long-living macroscale turbulence inside the plume and gives a real picture of the plume dispersion and transport. A simultaneous air speed measurement leads to the emitted mass concentration flux. This speed is often determined by correlation of video pictures of the aerosols contained in the plume or by correlation of the LIDAR returns themselves.

Note, however, that such 3-D mappings require relatively stable weather conditions, since the total measurement time in this case is 15 min. The atmospheric fluctuations in plume measurements by DIAL must therefore be carefully considered, so that the measurement time always fits the timescale of the monitored process. Microscale, fast fluctuations may also induce errors in DIAL measurements of emitters, since the wavelengths are usually sent alternately since they have to remain close to each other and thus cannot be spectrally separated in the detection chain. The switching time between the two wavelengths is critical because microscale fluctuations of concentration may be fast enough to induce errors. In the UV and for DIAL measurements other than plume tracking, it has been demonstrated that atmospheric fluctuations do not induce significant errors in the results and that shot noise is the major limitation.

If the characterization of identified emitters such as plumes is highly relevant in terms of impact on the environment, the use of DIAL systems in industrial environments is even more interesting for diffuse or unclassified emitters. An example of a toluene profile obtained over a petrochemical plant in Cubatao (Brazil) is presented in Figure 5. It clearly shows the diffuse emission of a storage tank of gasoline: the floating roof periodically exhausts some toluene bursts, which then move to higher altitudes. These emissions are usually very difficult to quantify or even to detect with standard techniques, although they may amount to as much as the classified emitters in some cases.

The most important source of diffuse and “moving” emission of atmospheric pollution is obviously road...
Figure 5 Diffuse toluene emission from a storage tank.\textsuperscript{(41)}

Figure 6 NO mapping over Lyons.\textsuperscript{(28)}

traffic, so extensive studies have been performed in urban conditions. In particular, DIAL measurement campaigns in large European cities have provided very important information about the influence of urban topography.\textsuperscript{(28)} Figure 6 presents a map of the NO concentration over the city of Lyons. Since Lyons is a relatively flat, well-ventilated city, the traffic-related pollution is efficiently spread, and the highest values (102 ppb) are recorded for narrow streets in the old part of the city, where a few vehicles are moving slowly, and not over the main avenues. Vertical gradients have been determined in these narrow street canyons: a dilution factor of 5–6 was usually recorded between the ground level and the canopy, attesting to the poor ventilation.

The topography of Stuttgart is opposite to that of Lyon, with a shape close to a “Mexican” hat, where the vertical air mass exchanges are strongly hindered. As a result, inversion layers, where air pollution is trapped, appear frequently, as shown in Figure 7. NO concentrations as high as 150 ppb have been recorded by DIAL inside this layer. Owing to the valley shape of the region, this layer reaches the outer residential quarters of Stuttgart more dramatically than the city center, although the primary NO pollutant is mainly emitted in the city center.

In addition to emission intensity and topography, meteorology also plays a crucial role in the distribution of air pollutants and in the formation of smog situations.
This is demonstrated in the case of Geneva in winter 1989. Figure 8(a) exhibits a typical smog situation, where high NO concentrations are recorded everywhere, without steep gradients, although NO is a primary, traffic-related pollutant. The concentrations increase almost without limit because of the lack of air motion. Two days later, a north wind destroyed this local equilibrium and blew the air masses out from the Geneva valley. This led to a return to a normal situation (Figure 8b), with steep gradients and lower concentrations. The Mont Blanc bridge, usually strongly subject to traffic jams, does not suffer too much, again because of good ventilation from Lake Geneva and the River Rhone. However it should be noted that the high value of 92 ppb remained over the English Garden ("Jardin Anglais"). It was found that this local maximum was due to the air conditioning system exhaust of the large underground car parking located under the Garden.

This example emphasizes the difficulty of obtaining a realistic picture of the air quality in a city with standard networks, and especially the difficulty of finding representative locations for spot analyzers. DIAL measurements provide very useful information in this respect.

An especially attractive application of DIAL is in tracing pollution in trans-border importation/exportation situations. An example of a study of this kind was performed during an intensive LIDAR campaign in Berlin in January 1989, in order to quantify the transport processes between East and West Berlin. At this time, the Berlin Wall still existed, and the West German pollution regulations were applied to West Berlin, although no sanitation actions could be taken in East Berlin. Even the concentration values of pollutants at ground level in East Berlin were not available. A typical result of this campaign is shown in Figure 9.

The directions in which the vertical profiles were recorded were chosen in the south-east (SE) wind direction and at 90° from it. In the SE direction (East Berlin) the SO2 values reach 140 ppb at ground level and then smoothly decrease with altitude until a set of inversion layers between 400 and 600 m. The emitted concentrations at ground level are mainly due to coal burners. In the north-west (NW) direction (West Berlin), ground level values are much lower, while at 600 m a maximum is found, demonstrating pollution transport processes. At 90° south-west (SW), the maximum is located at lower altitude, confirming the interpretation of importation from SE to NW.

A more direct importation process has been recorded, related to the power plant “Mitte” located in the center of East Berlin. For this, the DIAL system was placed at...
close to the former Berlin Wall, about 1 km from the emitter (Figure 10). The SO\textsubscript{2} plume was followed for over 2 km, delivering very precise information. Besides the mass concentration fluxes determined from DIAL measurements just at the chimney output, it could be clearly observed that, again, two burners were used, and that their related plumes did not mix with the distance. It was also shown that more than 500 ppb of SO\textsubscript{2} were “imported” over West Berlin from this emitter at that time.

Routine monitoring is also a standard application of LIDARs. A stationary DIAL system has been implemented in the center of Leipzig since 1992.

Figure 11(a) shows a typical map of SO\textsubscript{2} over the city. Such maps can be recorded hourly and give average information about air quality. However, if a higher concentration is observed in some direction, a “zoom” can be performed at higher spatial resolution (a few meters) and in three dimensions. The example of a power plant located 1.5 km from the station is shown in Figure 11(b). This allows us to determine the plume dimensions and dilution over more than 1 km, and then obtain a more accurate estimate of the effects of this particular emitter in the former low-resolution map, i.e. a direct correlation between emission and immission.

After these examples of accessing physical dynamics with DIAL, let us now focus on chemical and photochemical processes. As an example, we present here the results of a measurement campaign on ozone in Athens in summer 1994. Ozone is one of the most important pollutants responsible for the summer “smog” recorded in large urban areas. Its formation is particularly due to the emission of road traffic (nitrogen oxides, VOCs) combined with sunny periods. Photolysis is the dominant loss process for NO\textsubscript{2} in the troposphere and the major source of tropospheric O\textsubscript{3} (Equations 3–5):

\[
\begin{align*}
\text{NO}_2 + h\nu & \rightarrow \text{NO} + \text{O}^3\text{P} \quad (3) \\
\text{O}^3\text{P} + \text{O}_2 + \text{M} & \rightarrow \text{O}_3 + \text{M} \quad (\text{M} = \text{air}) \quad (4) \\
\text{O}_3 + \text{NO} & \rightarrow \text{O}_2 + \text{NO}_2 \quad (5)
\end{align*}
\]

In the absence of other processes that convert NO to NO\textsubscript{2} and assuming steady-state conditions, one obtains the well-known Leighton relationship [Equation 6]:

\[
[\text{O}_3] = \frac{j_3[\text{NO}_2]}{k_5[\text{NO}]} \quad (6)
\]

The ozone production depends in this very simple case on the solar irradiation-dependent rate \(j_3\) and the rate constant of Equation (5), \(k_5\). However, it has been shown...
that VOCs also play a key role in ozone formation, and in particular enhance the NO to NO₂ conversion and thus favor ozone production. A comprehensive description of the many reactions involving NOₓ and VOCs can be found in a reference book published by the National Research Council.\(^{54}\)

Ozone production is usually plotted in the form of isopleths as a function of the VOC and NOₓ concentrations. The isopleths have roughly the shape of a hyperbola, and the diagram characteristically exhibits a diagonal ridge from lower to higher concentrations. This ridge is more or less a straight line of a given VOC/NOₓ ratio. Depending on the value of the VOC/NOₓ ratio encountered in the atmosphere, the ozone production can thus be either NOₓ-limited (high VOC/NOₓ ratios) or VOC-limited (low VOC/NOₓ ratios). The location of the ozone maxima will thus be determined by the VOC/NOₓ ratio and not by the isolated NOₓ or VOC concentrations.

Athens is a very interesting example of ozone smog formation. Meteorological and photochemical dynamics are combined to form ozone in high concentrations. Athens is located in a basin, and thus subject to a back and forth motion of air masses from the sea to the ground. Hence cold wind flows from ground to sea in the night whereas a sea breeze moves the air masses back to the land inside during the day. The wind direction flips very fast from north to south at about 10 a.m. in summer, as shown by Grying.\(^{55}\) Simultaneously, the dense traffic emits high NOₓ concentrations which, together with the strong solar radiation and high temperature, favor ozone production.

DIAL measurements\(^{26,56}\) were performed in summer 1994 within the large-frame MEDCAPHOT campaign, the LIDAR system being located in the city center (Pnyx Hill). In order to access the ozone formation dynamics, both NO₂ and O₃ mappings were recorded. Figure 12(b) shows the 2-D NO₂ vertical map over Athens at about 10 a.m. Since solar radiation had just started to increase, the NO emitted by the road traffic was oxidized during the early morning (Equations 5 and 6), yielding a thick NO₂ layer near ground level, with concentrations exceeding 100 ppb. Half an hour later, the effect of wind flipping is observed: the sea breeze induces vertical advection of the NO₂ concentration (Figure 12a). The increasing ground temperature also contributes to this rising motion of the air masses.

In Figure 12(a), a secondary local maximum of NO₂ at about 1000 m altitude is clearly observable. This NO₂ is
then photodissociated by the solar radiation, generating ozone (Equations 3 and 4). This leads to the formation of an ozone storage layer, as presented in Figure 13. Ozone concentrations as high as 180 ppb are observed at around 1000 m altitude. Note that the concentration at ground level at this moment is only 50 ppb, owing to the local high NO concentration emitted by the dense traffic.
The meteorological dynamics take over again at the end of the beginning of the night, when the air masses fall again and transport ozone back to the ground. A detailed study of these dynamics and a comparison with numerical models was described by Weidauer.\(^{56}\)

The effects of vertical transport of the NO\(_2\)-producing ozone observed here can obviously also occur horizontally, in the surroundings of urban areas. The measurements in Seville within the frame of a campaign organised by the Joint Research Center Ispra\(^{33}\) have been mainly performed at three particularly representative sites. The first series of mappings was recorded in the town center. Profiles were measured along a road with major traffic, interrupted with many traffic lights. Results are presented in Figure 14(a). They show a moderate average ozone concentration of about 50 ppb with peaks at 80 ppb
Figure 14 (Continued)
at the beginning of the afternoon when solar radiation is maximum. During the night, the concentration stabilizes around 35 ppb, although it remains important at high altitudes. Again, without solar photodissociation of NO\textsubscript{2}, oxidation of nitrogen monoxide takes place, and yields a lower ozone concentration. In other words, as is often observed,\textsuperscript{54} the VOC/NO\textsubscript{x} ratio in the center of large cities is too low to obtain maximum ozone production.

The second series of measurements was performed in a rural area, La Riconada, upwind from Seville during the measurements. Results are presented in Figure 14(b). Concentrations were low, from 30 ppb during the night to 50 ppb in the day. This can be easily interpreted, since the Seville city plume is propagating in the opposite direction and thus almost no nitrogen oxides (and also O\textsubscript{3}) is imported. The population is weakly exposed compared with the population in the center of Seville.

The third site chosen for the LIDAR measurements was downwind from Seville at the measurement time, in a totally rural zone, 22 km from the city. This region is well known for its agricultural production. Long-distance transport of the Seville nitrogen oxides then encounter a totally rural zone, 22 km from the city. This region is well known for its agricultural production. Long-distance transport of the Seville nitrogen oxides then encounter

The results presented here show precisely on the one hand the influence of the meteorological conditions on ozone formation, and on the other hand the importance of transport processes of urban pollution. They also show that some legal reduction actions on nitrogen oxide or VOC emissions may lead to a geographical shift of the ozone maxima and not to an overall reduction.

In the whole discussion above, the effects of aerosols on the ozone production could not be taken into account, since their action is not fully understood. Quantitative measurements of aerosols by LIDAR are thus an important challenge, as described below.

5 DETECTION OF AEROSOLS AND DUST PARTICLES

The impact of atmospheric aerosols on public health and in heterogeneous chemistry is well recognized, although few conclusive studies have been reported so far. This is especially true for urban aerosols, the variety of which in size and composition makes complete characterization difficult. We present here a combined technique, using LIDAR measurements, scanning electron microscopy (SEM), and X-ray microanalysis.\textsuperscript{57} Urban aerosols are first sampled using standard techniques on different filters. Their size is determined by SEM and counting and their composition by X-ray microanalysis. The size distribution exhibits mainly two modes: one around 0.1 \(\mu\)m constituted of soot and sulfates and the other around 1 \(\mu\)m composed half of larger soot aggregates and half of silica particles.

These data are then used to compute optical backscattering and extinction coefficients, leaving as the only unknown parameter the total number density of particles. The basis of the determination of the optical scattering coefficients \(\alpha\) and \(\beta\) is a newly developed model, based on a fractal theory for small soot particles (from 50 nm to 0.5 \(\mu\)m) and on a modified Lorentz–Mie theory for larger particles such as silica.\textsuperscript{50} The larger soot aggregates are considered as spheres made of lacunary media, with 50% carbon and 50% void.

Number-density profiles over Lyon were obtained by simultaneous LIDAR measurements using an eye-safe LIDAR system (frequency doubled Ti:sapphire laser-based system at 390 nm). The LIDAR data were inverted with the backscattering and extinction coefficients computed from the actual size distribution. These measurements were performed in the frame of an intensive campaign in summer 1996 in Lyon, in collaboration with the Departement d’Ecologie Urbaine of the City of Lyon. LIDAR data were inverted using a Klett algorithm\textsuperscript{37,38} with two reference points, one located close to the ground with the \(\alpha\) and \(\beta\) values determined above, and the other at high altitude where a clear atmosphere is assumed. In the conditions encountered here, the assumption of an average shape of the size distribution is acceptable (warm, stable afternoon). This could be confirmed by a parallel epidemiological study, involving 30 volunteers with transportable samplers.

Quantitative 3-D distributions of aerosols over the city have been obtained with this method for the first time. The results show a fairly homogeneous mixing layer up to 1300 m. An interesting measurement is also the temporal dependence of the concentrations of these urban aerosols. Figure 15 shows the evolution of the vertical profile of aerosol concentration in Lyon over 24 h during a high-pollution episode, on June 27–28, 1996. It shows very clearly the motion of the mixing layer height. Owing to the temperature changes, the mixing layer top drops to 200 m during the night and rises to 1300 m in the early afternoon. Traffic jams also induce
an increase in the aerosol density during rush hours, in
the morning around 8 a.m., at noon, and in the evening
around 6 p.m. Even 80 m above ground, concentrations
as high as 40 µg m\(^{-3}\) are observed during these rush
hours.

6 VALIDATION OF NUMERICAL MODELS

A task of increasing importance for LIDAR systems is
the validation of numerical models. This applies both to
microscale dispersion models and to regional-scale codes,
which provide output data averaged over grid cells several
kilometers long.\(^{54}\)

Verification of numerical model predictions has been
performed both for microscale plume dispersion codes
and for regional-scale Lagrangian/Eulerian models during
a large frame campaign in the Swiss Rhone Valley.\(^{46}\)
Since both models tested did not include a chemical
module, the pollutant chosen for the comparison was a
relatively non-reactive species, SO\(_2\).

The verification of the plume spread model was
performed on the emission of a power plant, where
3-D mappings of the plume were recorded at high
resolution and the concentration was averaged over
sections perpendicular to the plume direction. This
gave a good estimate of the plume dilution with
distance (Figure 16). Owing to the windy meteorological
conditions, the emitted SO\(_2\) concentration is rapidly
spread and transported in a rather flat plume of about
120 m width for only 30 m height. A typical dilution value
is 30 at a distance of 100 m.

---

**Figure 15** Temporal evolution of the aerosol mass concentration measured by LIDAR.

**Figure 16** Verification of a plume spread model by DIAL measurements.\(^{46}\)
meteorological conditions and the emitter characteristics (plume exhaust velocity, temperature, initial \(SO_2\) concentration), one then retrieves the concentration in each grid cell. The agreement between DIAL data and numerical simulations is excellent. This is made possible only through the careful analysis of a very large number of Lagrangean particles (31^3) and the high density of the receptor grid (1 m\(^3\)) located along the plume axis in order to estimate dilution. It can be seen, however, that the initial concentrations are overestimated by the numerical model in the vicinity of the chimney exhaust. This difference may be produced by the presence of numerous aerosols (especially water droplets), on which some \(SO_2\) molecules are adsorbed. The \(SO_2\) concentration, measured by DIAL, is then lowered at the benefit of other compounds, which are not measured.

Note also that if the model is verified for some section of the plume, it can be used in turn for the dispersion at longer distances, where DIAL data are no longer available. The LIDAR–model combination can thus be very useful and complementary for long-distance transport studies.

The verification of the large-scale model (MESOCONV\(^{(40)}\)) was carried out in the Chablais Valley, a fairly wide channel, completed by several smaller and colder perpendicular valleys, which often leads to a multilayered stable situation. The emitted pollution can therefore be trapped in one of these sublayers without any mixing with the others. The pollution concentration is then highly dependent on altitude, and it is of great importance for vegetation damage to monitor whether the maxima always occur at the same levels above ground. Several \(SO_2\) emitters are present at ground level, and also a highway which follows one of the edges of the valley.

On the day of the experiment, winds were light (3–5 m/s) and blowing down-valley towards Lake Geneva. A very strong temperature inversion was located at about 450 m above the valley floor, at 850 m above sea level. This inversion plays a fundamental role, of course, in the distribution of pollutants within the valley. A comparison between DIAL data and results of the model is shown in Figure 17. For this, vertical profiles, averaged over the horizontal paths across the valley, were both calculated and measured. An excellent correlation was again found at the mesoscale level, under immission conditions. It can be seen that, even for a receptor located some 12 km from the southernmost sources, the value of the peak concentration and its height above the ground correspond very well with the observations. Above the peak value, which is located at the inversion level owing to trapping by thermal stability, as was explained previously, the DIAL system detects nonzero pollution which is not computed by the numerical model. This upper-level pollution is in effect a feature of pollution from the previous day which was diffused at height but which remained at upper levels owing to alternating up- and down-valley flow which recirculates the pollutants. The numerical model computed only the contribution to pollution from emissions on the day chosen for this case study, and consequently contains no background pollution, which is a measure of the recent “history” of air quality in the region studied. This can be of advantage when attempting to identify the contribution of a particular source to global pollution of multiple origin. Conversely, it may be criticized that the absence of background pollution in the model leads to results which do not correspond to reality.

7 COMPARISON WITH OTHER TECHNIQUES AND CALIBRATION PROCEDURES

Calibration of LIDAR systems is an important but difficult issue, since path-averaged data (within the used spatial resolution) have to be compared with spot reference measurements. Note that the same problem applies to other optical techniques such as open-path FTIR spectroscopy and differential optical absorption spectroscopy (DOAS).

The success of comparative measurements between DIAL and spot reference data depends directly on the concentration gradients present in the atmosphere.\(^{(59)}\) In homogeneous conditions, i.e. sites far from emitters, comparative studies can be performed without particular
difficulties. An example of such a study has been performed on ozone by Goers\textsuperscript{56} in the forest of Albstafelde (Germany). The LIDAR data were compared with standard analyzer data (UV spectrophotometry) collected at different altitudes on a tower, located 1030 m from the LIDAR system. The laser beam was steered to pass near the tower at the altitude of the 47-m high spot measurement. The results, which are presented in Figure 18, show very good agreement (within ±3 µg m\(^{-3}\)) between the LIDAR measurements and standard analyzer data.

Other favorable conditions are emission measurements. The high concentration (at chimney tops, for example) allows DIAL measurements at maximum spatial resolution, which again compare well with the in situ spot data.

Difficult cases are urban conditions. The steep gradients and the concentration levels necessarily require path averaging of fluctuations for the DIAL technique and extremely critical location for the reference analyzers. Comparison strategies therefore have to be carefully developed for these situations. The most critical case is the detection of primary pollutants emitted by road traffic, such as NO. An example of comparison strategies in the latter situation was performed in Stuttgart in 1989 (Figure 19). The spot NO analyzer was located at about 20 m altitude on the top of a building in the city center while the DIAL system beam was directed at it. The observed concentration evolutions as a function of time are remarkably close. However, the absolute concentration values from the DIAL system are still systematically lower by about 15% than the spot data. This is due to the spatial averaging mentioned above, since the LIDAR spatial resolution (50 m) includes lower concentrations from higher altitudes.

Comparison with spot analyzers is a valuable calibration method but the tests performed on the system are limited to the concentration levels present in the atmosphere during the measurements. An attractive alternative technique is the use of reference gases. A cell is then located in the DIAL measurement path, in which calibrated concentrations of reference gases are introduced. This induces a supplementary absorption in the light path to the absorption from the atmospheric pollutant, and the difference from a second empty cell provides the reference gas concentration. This technique was used very successfully by the Institut National de l’Environnement et des Risques (INERIS) in Verneuil-en-Halatte for the evaluation of commercial DIAL systems.\textsuperscript{61,62} The usual normative parameters\textsuperscript{63,64} such as detection limit, linearity, repeatability, zero, cross-sensitivity, and interferences, could be determined with this method. As an example, Figure 20 shows the excellent results of the linearity measurement obtained on SO\(_2\). It is important to note that
similar techniques are used today for the calibration of DOAS and FTIR devices, so that a standard calibration procedure can be determined for all open-path optical methods.

8 NEW LIGHT DETECTION AND RANGING STANDARDS

Advances in technology and the advent of commercial systems recently accelerated the normative actions for DIAL systems. Prenormative activities such as the above-mentioned evaluation by INERIS or campaigns from the European Joint Research Center in Ispra[33] have also greatly supported the norms. Pioneering work was performed by the VDI/DIN commission in Germany from 1992 to 1997, which yielded the first normative text for DIAL systems.[18] A similar action is in progress at the European level for the Commission Européene de Normalisation (CEN). These actions are of crucial importance for the wide use by EPAs of this very attractive technique.

9 CONCLUSION

We have presented an overview of today’s capabilities of LIDAR systems to provide 3-D profiles of concentrations of gaseous and particulate pollutants and temporal evolution. New normative actions are recognizing the unique advantages of this technique and show the way to operate and calibrate the available systems properly. More than 20 years after the first LIDAR mappings of gaseous species, the wide use of DIAL systems for monitoring air pollution has today been achieved.

Environmental Analysis of Water and Waste: Introduction

Marvin P. Miller
Dow Chemical, Midland, USA

The field of environmental analysis is driven by demand for development of analytical methods providing ever-increasing specificity and throughput, decreases in detection limits, and improvements in precision and accuracy. Typically, meeting these conflicting demands requires a compromise of some type. The methods with the lowest detection limits are seldom those that simultaneously provide the best specificity or most cost effective analysis. Concurrently, the number of analytes of interest in environmental samples continues to expand rapidly while the type and complexity of samples grows as well. Thirty years ago, most environmental analyses were conducted on water samples with perhaps 10-15 analytes per sample. Today samples of interest include water, waste water, soils, solid or liquid waste, and biological materials, and at times the list of analytes to be determined can number several hundred. For these reasons, the variety of analytical methodology utilized for environmental analysis is extensive. The number of approved methods by the United States Environmental Protection Agency (USEPA) alone exceeds several hundred. This section will provide a comprehensive overview of modern environmental methodology for the analysis of water and waste samples. Articles will describe both the application of a wide variety of instrumental methodology, as well as techniques for determination of an extensive array of parameters in many different matrices, including water, waste water, soils, hazardous wastes, and biological materials. Methods specific to field analysis are presented in the section entitled Field-portable Instrumentation.

Development of environmental analytical methodology, especially those methods in common usage, has frequently been driven by monitoring regulations and requirements. This is especially true in the United States, where the passage of numerous acts has led to the creation of a variety of target analyte lists. The Federal Water Pollution Control Act or ‘The Clean Water Act’ (1972) led to lists of analytes to be determined in wastewater discharge streams. As a result of a subsequent law suit, “N.R.D.C. vs. Train, 8ERC2120”, an extensive list of 129 parameters was established and analysis of this entire list was required for all discharge streams. The Safe Drinking Water Act (1974) resulted in another specific list of 14 parameters that were to be determined in drinking water samples. The Resource Conservation and Recovery Act (1977) and subsequent amendments introduced the Appendix VIII and Appendix IX lists of target analytes for waste and groundwater samples. These list several hundred specific parameters or categories.

In some cases when these lists where first developed, the analytical methodology did not exist to make accurate determinations in the complex matrices of interest. Thus, the legally mandated analyte lists drove the development of more sensitive and selective methods in many areas. Furthermore, enforcement of these laws created tremendous numbers of samples to be analyzed, which created the demand for methods with faster throughput. Thus, the rapid advancements in the field of environmental analytical chemistry and the adoption of sophisticated methodology were in many ways the result of regulatory requirements. For example, early analysis of wastewater samples for many organic species was conducted by a variety of gas chromatographic techniques, requiring several separate analyses to complete one sample. The development of the gas chromatography/mass spectrometry (GC/MS) methods 624 and 625 provided more specific analysis of the organic parameters on the priority pollutant list with only two determinations. Initially, few laboratories had access to expensive, sophisticated GC/MS methods. However, the large volume of samples requiring analysis across the world quickly drove demand for improvements in the instrumentation. Today, GC/MS is relatively inexpensive and is part of every well-equipped environmental laboratory. A similar situation has occurred for the determination of elemental species. The use of inductively coupled plasma (ICP) and ICP coupled with a MS (mass spectrometry) detector (ICP/MS) has greatly enhanced the sensitivity and speed of analysis relative to the use of flame and flameless atomic absorption spectrophotometry.

As is the case in all fields of analytical chemistry, a critical component in environmental analysis is to conduct all determinations under the guidance of a carefully designed quality assurance (QA) program. In many cases, environmental analyses also must be conducted following strictly designed regulatory requirements, dictating such things as sampling and analysis methodology, quality control procedures, and complete documentation policies. Specific legally mandated QA requirements can vary significantly depending upon many parameters, including the country, the regulating agency, and the sample type. While the specific QA requirements can change, the fundamental concepts of QA do not. The introductory article in this section, Quality Assurance in Environmental Analysis, written by Malcolm Clark of the Canadian Ministry of Environment, provides a comprehensive discussion of the primary elements of QA. The author covers QA requirements from initial program design through sample collection, analysis, and final reporting. He also discusses
types of errors that can occur and means of determining detection limits. The use of certified reference materials, interlaboratory testing and legal QA requirements are discussed, and the author discusses the use of performance based methods, an area of particular emphasis in recent years for the USEPA. Robert Gibbons in Detection and Quantification of Environmental Pollutants provides a detailed discussion of a number of means to express detection and quantification data, including applications to limit both false positive and false negative results.

No matter how carefully the environmental analytical chemist conducts the laboratory determination, the quality of the data is totally dependent on the quality of the sample taken. The sample must be representative of the body it represents and it must be maintained in the appropriate manner to prevent contamination and/or deterioration of the analytes of interest. Once again, the vast array of sample matrices and analytes leads to the requirement for many different sampling protocols to meet the above requirements. The following series of articles covers the requirements for sampling in a variety of matrices of environmental interest.

Biological samples can provide an excellent indication of exposure to pollutants, as discussed in Biological Samples in Environmental Analysis: Preparation and Cleanup by Steven Barker. Barker further describes means for biological sample preparation and cleanup, including gel permeation, super critical fluid extraction, and solid phase extraction. Sampling for biological monitoring requires additional considerations in order to ensure the appropriate data are collected. Sampling Considerations for Biomonitoring are covered by Tim Koeckritz et al. who focus on three key axioms for sampling, i.e. chemical composition, distribution of organisms, and the economic aspects of the information content. While these axioms were developed for biological materials, they are nonetheless relevant with minor modifications to all types of sampling programs.

Soil Sampling for the Characterization of Hazardous Waste Sites is discussed by Brian Schumacher et al. who begin with a discussion of how to plan the sampling program, including definition of the data quality objectives for the program. They discuss considerations for selecting the appropriate spatial sampling strategy and ways to estimate variance. Site mapping, site characterization, and sample collection are described, as well as selection of sampling equipment. Industrial Waste Dumps, Sampling and Analysis is the topic of the next article, written by Winfried Rasemann. He discusses some of the basic problems encountered in sampling industrial waste dumps and examples of how these problems can be avoided by statistical evaluations.

Environmental analysis can be divided into three primary categories; organic, inorganic, and ‘conventional’. The term conventional is used to describe a variety of determinations that include total carbon, biological oxygen demand, and in some cases ionic determinations by such techniques as ion selective electrode (ISE) or ion chromatography (IC). Asbestos analysis does not fit well in any of these categories, however the widespread use of asbestos in the past and the well-known hazards of exposure makes this a determination of particular interest around the globe.

Norber Hofert discusses the determination of airborne asbestos fibers and asbestos in bulk materials and drinking water in the article Asbestos Analysis. The use of scanning, transmission, and phase contrast microscopy is described, as well as the use of X-ray diffraction and infrared techniques.

The determination of total and dissolved organic carbon is one of the most commonly used methods for quickly assessing the overall water quality. Kenneth Mopper and Jian-guo Qian, compare the two primary methods, wet oxidation and high temperature combustion, and examine problems encountered when analyzing sea water in the article Water Analysis: Organic Carbon Determinations. The use of ISEs is widespread in environmental determinations for a large number of analytes. Ion-selective Electrodes in Environmental Analysis are described by Robert Forster and Tia Keyes. The authors discuss the advantages of ISEs (portability, sensitivity, wide dynamic range, ease of use, continuous measurement, etc.) They provide a theoretical background for the technique, and a detailed discussion of the various types and applications of ISEs, including determination of metallic species as well as anions and cations. A comprehensive table of analytes and sensitivities that can be achieved with ISEs is provided.

The next series of articles in this section cover the determination of elemental species by a variety of techniques. The series begins with four articles on different sample preparation procedures used on various matrices. First, Sergio Marin discusses Sample Preparation Techniques for Elemental Analysis in Aqueous Matrices. Discussions are provided on proper sample collection, handling, and storage, as well as appropriate laboratory conditions for minimizing the potential for contamination. A variety of digestion or extraction procedures are discussed, including wet digestion, dry ashing, sequential extraction, and pressurized digestion. Sample Preparation for Environmental Analysis in Solids (Soils, Sediments, and Sludges) is described by D. Kimbrough beginning with a discussion of ways to physically prepare the samples (milling, sieving, etc.). Kimbrough reviews several USEPA acid digestion procedures and discusses the application of each to different matrix types. He also describes methods for extraction of organic compounds from solids using solvent extraction.
The preparation of biological samples for elemental analysis requires special consideration and is described by Kunnath Subramanian in the article entitled Sample Preparation for Elemental Analysis of Biological Samples in the Environment. Protein precipitation, chelation, and solvent extraction are discussed, as well as a variety of procedures to remove the organic matter from the samples. Specific considerations are provided as a function of the element of interest, the sample matrix (e.g. urine, hair, bone, tissue), and the instrumentation to be used (e.g. ICP, ICP/MS). Mehdi Ashraf-Khorassani, Larry Taylor and Michael Combs, provide their insight on the use of Supercritical Fluid Extraction of Inorganics in Environmental Analysis. While direct extraction of cationic metal ions is not feasible with supercritical CO₂, in situ chelation of the metal ions can enhance the extraction efficiency. The authors examine the solubility of different ligands and metal chelates in supercritical fluids and assess the impact of the matrix as well.

The next series of articles covers a variety of instrumental techniques used for the determination of elemental species. Perhaps the most commonly used, and certainly the instrumental technique that has the longest history, is the use of atomic absorption spectroscopy (AAS), both by flame and graphite furnace. This topic is covered extensively by Michael Sperling. Flame and Graphite Furnace Atomic Absorption Spectrometry in Environmental Analysis starting with a comparison of detection limits for both flame and furnace AAS. Sperling provides a very useful summary of instrument fault recognition and means for optimization of the instrument. Spectral and nonspectral interferences and AAS specific QA are described. Sperling follows with a comprehensive discussion of the application of both flame and furnace AAS for analysis of waters, soils and other solid materials.

For certain elements with higher volatility (e.g. arsenic, selenium), conventional flame and furnace AAS techniques may not provide adequate sensitivity for some environmental concerns. One means to improve the sensitivity for these parameters is by use of hydride generation for sample introduction. Hisatake Narasaki discusses in Hydride Generation Sample Introduction for Spectroscopic Analysis in Environmental Samples, including proper sample preparation, detection limits and application to not only AAS but also both optical emission ICP and ICP/MS.

Scott Baker and Nancy Miller-Ihli describe another sample introduction technique that can be used to enhance sensitivity, particularly for solid samples, Slurry Sampling Graphite Furnace Atomic Absorption Spectrometry in Environmental Analyses. The use of slurry sampling into the graphite furnace is described, including methods for producing and optimizing slurries of a variety of matrix types. Instrumental conditions are described and examples of environmental applications are given, as well as comparisons to other direct analysis methods.

The determination of mercury is of particular interest due to its toxicity and propensity to bio-accumulate. Unfortunately, neither flame nor graphite furnace AAS can provide a detection limit adequate for determination of mercury at levels of environmental concern, typically in concentrations of low to sub-part per billion. The most commonly used technique Mercury Analysis in Environmental Samples by Cold Vapor Techniques, is discussed here by Kim Anderson. The author describes the sample preparation technique, and the use of the specific instrumentation required, as well as sensitivities and common interferences. The sensitivity of cold vapor (CV) AAS is compared with other potential techniques, such as atomic fluorescence spectroscopy (AFS), and a summary of mercury regulatory standards around the world is given.

While AAS is an extremely valuable technique, the throughput is limited, particularly when using the graphite furnace. The introduction of inductively coupled plasma atomic emission spectroscopy (ICPAES) led to the rapid advancement of methodology to take advantage of the simultaneous multi-elemental analysis capability while providing detection limits equivalent or better than graphite furnace AAS. Optical Emission Inductively Coupled Plasma in Environmental Analysis is described by Mark Tatro. The author outlines available USEPA ICPAES methods and discusses means for overcoming common interferences. ICPAES specific QA requirements are also described.

In some cases, even ICP optical emission spectroscopy cannot provide sufficient sensitivity or specificity for certain elements in certain matrices. For example, optical ICP generally cannot be used for determination of arsenic, selenium, and mercury in drinking water samples because the detection limits are not adequate. The development of ICP coupled with a mass spectrometer as a detector provides an additional tool with enhanced sensitivities for many elements. Inductively Coupled Plasma Mass Spectrometry in Environmental Analysis is described by S. Yamasaki who reviews the instrumentation and provides an overview of the types of sample introduction used with ICP/MS. The typical detection limits are provided for elemental analysis of environmental samples in water, soils, and biological materials. The author also describes the use of high resolution ICP/MS which can be used to provide enhanced selectivity.

The determination of specific elemental forms is described by Wang Xiaoru and Frank Sen-Chun Lee, in their contribution entitled Capillary Electrophoresis Coupled to Inductively Coupled Plasma-Mass Spectrometry for Elemental Speciation Analysis (CE/ICP/MS). The authors describe optimization of the capillary
electrophoresis (CE) separation procedure and compare the technique to conventional ICP/MS. A comparison is made of a number of nebulizers that have been used for CE/ICP/MS.

Conventional ICP or ICP/MS analysis requires the dissolution of the sample for introduction into the instrument as a solution. In addition to the time required for sample preparation, the dissolution can result in decreased sensitivity. Laser Ablation Inductively Coupled Plasma Spectrometry in Environmental Analysis, as described by Steven Durrant, can provide a means for the direct vaporization of a solid sample and subsequent introduction into either an optical ICP or ICP/MS. The author describes several laser ablation systems and provides analysis procedures, including its use for samples of environmental interest, such as metals, geological, and biological materials.

In some cases, it is of interest to detect organic species containing specific elements. Stig Pedersen-Bjergaard has provided an article on Gas Chromatography with Atomic Emission Detection in Environmental Analysis. The column first separates the organic species and the elemental detector can be tuned to the parameter of interest. The author describes the selectivity and sensitivity of the method, as well as a compound independent calibration. He provides examples of several environmental applications for compounds containing specific elements such as tin, lead, and mercury, as well as the use for other compounds containing non-metallic elements.

Yong Cai discusses the use of another alternative technique for elemental analysis, Atomic Fluorescence in Environmental Analysis. AFS can provide enhanced detection limits for some elements, and is of particular interest for the ultratrace level determination of mercury. In AFS, the sensitivity is directly proportional to the intensity of the light source, thus the author describes the use of hollow cathode lamps, electrodeless discharge lamps, xenon arc lamps and lasers. The determination of mercury by AFS is covered in detail, including methodology for organometallic determination of mercury species. Hydride generation is also described as a means to further enhance sensitivity and selectivity for volatile elements such as arsenic and selenium.

Flow-injection Techniques in Environmental Analysis are described by J.L. Burguera and M. Burguera. The authors describe how flow injection spectrophotometric methods can be used as alternatives to AAS and ICP techniques. In addition, the authors describe how flow injection can be used in conjunction with other instrumental methods such as AAS or ICP. A comprehensive list of the use of flow injection in environmental analysis is provided.

A recent addition to the tools used in environmental analysis for separation of complex samples, CE, is discussed by Yang Sun Kim in the article Inorganic Analysis in Environmental Samples by Capillary Electrophoresis. The author outlines the use of this technique for environmental samples, specifically for the determination of anions, metal speciation, metal complexes, and organometallic compounds. Comparison is also made with alternative methods such as IC, ICP and ICP/MS.

Inorganic Environmental Analysis by Electrochemical Methods offers an alternative to the commonly applied spectroscopic methods for the determination of many elements in a variety of matrices. This technique is discussed by Guler Somer. Polarographic and voltammetric methodology is covered, and application to air, drinking water, rivers, lakes, sea water, and wastewater, as well as for soil and sediment, is reviewed.

The determination of inorganic anions, cations, transition metals and low molecular weight organic acids and bases by IC is described by Peter Jackson in the article Ion Chromatography in Environmental Analysis. The author provides a brief history of the technique and a comparison with alternative methodology. Sampling handling, preservation, preparation and clean-up are described, and the use of IC in regulatory methods is covered, including specifics for inorganic anions, hexavalent chromium, cyanide and others. The use of IC for a variety of matrix types such as water, brines, soils, and sludge, is discussed.

Neutron activation analysis (NAA) provides excellent sensitivity, multi-element capability, ease of sample preparation, and freedom from interferences. However, it also requires access to a reactor facility in order to irradiate the samples. This powerful technique is discussed by Keith Randle, in Neutron Activation in Environmental Analysis. The author provides a brief history of the technique, followed by a discussion of the use of NAA for environmental samples with a table of ideal sensitivities. Application to biological samples is also discussed. The focus of the article is on the analysis of water samples by NAA, as well as the analysis of soils and sediments.

Another alternative technique for the determination of elements in environmental is samples is Proton-induced X-ray Emission in Environmental Analysis, or PIXE. Like NAA, PIXE provides simultaneous determination of a large number of elements and high throughput. However, as described by Grazia Ghermandi, in order to achieve sensitivities of environmental interest, a pre-concentration technique is frequently required. The author describes the methodology and its application to environmental samples such as water, sediments, and atmospheric aerosols. Matrix effects and interferences are discussed, as well as typical detection limits and
ranges for a variety of elements. The author also outlines the procedure to follow to develop a method for environmental analysis using PIXE.

**X-ray Fluorescence Spectroscopic Analysis of Liquid Environmental Samples** is the title of the next article, written by Philip Russell. The author includes descriptions of energy dispersive (EDXRF), wavelength dispersive (WDXRF), and total reflection X-ray fluorescence (TRXRF) and their use in the elemental analysis of natural waters, waste waters, hazardous wastes, and samples of interest to the nuclear industry. A section is also included on development of both EDXRF and WDXRF methods and on comparison with other spectroscopic methods.

**Heavy Metals Analysis in Seawater and Brines** is of particular interest due to the desire to study bioaccumulation of these parameters. However, because of the high salt content of the matrix, special procedures have been developed to minimize the matrix effects. Osvaldo Troccoli reviews this topic. Preconcentration and separation are described, as well as the most commonly encountered interferences observed using atomic spectroscopic techniques. A comparison is given among the spectroscopic procedures and electrochemical methods.

The primary focus of the determination of elements in environmental samples continues to be on the determination of the total amount of the element present, regardless of the oxidation state or the specific compound present. However, as more information has become available on the significant variation in toxicity of different organometallic compounds containing the same element of interest, methods have been developed to determine specific organometallic compounds as they occur in the environment. **Organometallic Compound Analysis in Environmental Samples** is addressed by Les Ebdon and Andy Fisher. The authors describe specific issues that must be considered when collecting and storing samples for subsequent analysis for organometallic compounds. Sample preparation procedures are given to extract the analyte of interest from liquid or solid samples. In some cases, a derivatization technique may be required in order to ensure that the analyte is in the appropriate form. A variety of analysis techniques are described, including both GC (gas chromatography) and LC (liquid chromatography) coupled with atomic spectrometry, and CE coupled with atomic spectroscopy. QA requirements specific to organometallic analysis are also discussed.

The overall characteristics of soil quality and a summary of soil analysis methodology is provided by M.R. Carter et al., in their article entitled **Soil Instrumental Methods**. The authors describe proper soil sampling procedures and statistical sampling methods, as well as discussing chemical, biochemical, and physical testing procedures.

As is the case for inorganic parameters, the determination of organic species of environmental interest frequently requires some means of specialized sample preparation in order to separate the analyte of interest from complex matrices. The first article in this section of sample preparation, ** Soxhlet and Ultrasonic Extraction of Organics in Solids**, contributed by G.R. Barrie Webster, provides a comparison of two primary extraction procedures for solid materials, ultrasonic and Soxhlet extraction. A comparison is made between USEPA methods and alternate procedures and specific QA and trouble shooting considerations are discussed.

Another alternative extraction procedure for organic species is discussed in the article, **Solid-phase Microextraction in Environmental Analysis** is provided by J. Pawliszyn. Two distinct solid phase microextraction (SPME) coating types are discussed, and a theoretical description of their use is given. The use of SPME for field analysis with a portable GC to determine volatile organic compounds (VOCs) in groundwater, soil, and air. Field evaluations of recently developed prototype systems are described.

The use of microwave energy to assist in solvent extraction of organic species is the topic of two articles. First, Frank Smith and Guohua Xiong have contributed the article entitled **Microwave-assisted Techniques for Sample Preparation in Organic Environmental Analysis**. The authors provide an extensive review of the use of microwave assisted extraction for a wide variety of organic parameters of environmental interest in soils, sediments, plant tissue, air and aqueous matrices. They also cover the use of focused microwave assisted Soxhlet extraction, microwave heating headspace analysis, and microwave-assisted derivatization. John Dean in his article entitled **Microwave-enhanced Solvent Extraction of Organics in Environmental Analysis**, discusses the theoretical basis of microwave extraction of organic analytes and describes both atmospheric and pressurized microwave extraction techniques. Comparisons are made with Soxhlet, ultrasonic, and supercritical fluid extraction (SFE) for polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and pesticides in standard reference materials and other samples.

In the article, **Supercritical Fluid Extraction of Organics in Environmental Analysis** Bruce Benner provides a theoretical discussion of supercritical fluids and their use for extraction of organic species from complex matrices. Reviews of several models of the supercritical extraction process are given, followed by a description of the instrumentation commonly used for SFE. An extensive review of the use of SFE for a wide range of organic classes is provided, including PCBs, pesticides, PAHs,
and hydrocarbons. Studies of extractions conducted on standard reference materials are discussed, comparing SFE with other extraction procedures.

Membrane-based non-chromatographic continuous separation techniques can also be used in environmental analysis for increased selectivity. Pervaporation, Analytical by M.D. Luque de Castro and L. Gamiz-Gracia reviews the principles of pervaporation and its use in analytical separation. The laboratory scale pervaporator is described, including a discussion of various membranes that can be used for different analytes. The sensitivity and selectivity of pervaporation is compared with headspace analysis and systems for multi-determinations are described.

GC is likely the most commonly used methodology for the determination of organic species in environmental samples. The need to determine a variety of classes of organic compounds at very low concentrations in frequently very complex matrices has led to the development of many selective detectors, each with specific advantages for certain compound classes. In Trace Organic Analysis by Gas Chromatography with Selective Detectors, Erwin Rosenberg provides a review of selective GC detectors, including electron capture, nitrogen-phosphorus, flame photometric, photoionization, and electrolytic conductivity (Hall) detectors. The operating principles and applicability of each type are discussed, as well as relative sensitivities. The author also provides a review and comparison of mass spectrometric, Fourier transform infrared, and atomic emission detectors for GC. Hiroyuki Kataoka provides specific focus on the use of selective detectors for the determination of amines in Gas Chromatography with Selective Detectors for Amines. The use of thermionic, flame photometric, electron capture, chemiluminescence, electrolytic conductivity, and mass selective detectors for various amine compounds is reviewed, with comparisons of sensitivities and applicability to aliphatic, aromatic, heterocyclic, and nitrosamines.

Most methods for the determination of organic compounds in aqueous samples requires some means of pre-separation from the matrix, such as solvent extraction, headspace analysis, or solid phase extraction. However, some water soluble analytes cannot easily be separated by these means, or it may be desirable to limit alteration of the matrix. Marek Biziuk has contributed Gas Chromatography by Direct Aqueous Injection in Environmental Analysis, a method requiring no separation prior to analysis. The author reviews techniques for direct aqueous injection onto both packed and capillary columns, including discussions of selectivity, sensitivity, and applicability. On column injection is discussed, including application to determination of haloforms in water using electron capture detection. Data are provided for the use of direct aqueous injection in determining organohalogen parameters in tap, surface and swimming pool waters, and for the determination of semivolatile and nonvolatile compounds.

While GC can be used with a variety of selective detectors to provide excellent sensitivity, in some cases the selectivity is not sufficient for positive identification of specific analytes due to the potential for co-elution of multiple compounds, even with the excellent resolution of modern capillary columns. By using a mass spectrometer as a detector for GC, another dimension is provided, allowing identification based on unique mass fragmentation patterns. Trace Organic Analysis by Gas Chromatography with Quadrupole Mass Spectrometry, contributed by Matthew Booth and David Powell, provides a review of the history of the development and use of GC coupled to quadrupole MS. The two principle methods of ionization, electron and chemical, are described, and sample preparation techniques for volatile and semivolatile analytes are reviewed. Special considerations are given for the use of GC/MS instrumentation.

While GC/MS is a very powerful technique for the determination of volatile and semi-volatile compounds, many organic compounds of environmental interest cannot be determined because they are non-volatile, polar, thermally labile, or ionic. M. Careri discusses the coupling of LC to MS, in Liquid Chromatography/Mass Spectrometry in Environmental Analysis. The author reviews types of instrumentation used for LC/MS, LC/MS/MS (tandem mass spectrometry) and LC/ICP/MS and their application for the environmental determination of pesticides, PAHs, dyes, surfactants, and organometallic compounds.

Organic acids are wide spread in the environment, and cannot be determined at trace levels via GC methods. Sigrid Peldszus has provided Organic Acids Analysis in Environmental Samples, Ion Chromatography for Determination of. The author reviews sources and samples of interest for organic acids, such as drinking water, waste water, and landfill leachates. The application of IC is discussed and sampling and preservation procedures are provided for various matrices. Specific sample preparation and analysis procedures are reviewed for air, drinking water, wastewater, and ground water samples, and comparison of IC with other methods or analysis of organic acids is given.

The next four articles describe alternate analytical methodologies that can be applied for the determination of organic analytes in environmental samples. Tom Viser has provided Infrared Spectroscopy in Environmental Analysis, where the author reviews application of infrared analysis to determination of a variety of VOCs in indoor air, atmospheric, and stack samples. In Organic Analysis in Environmental Samples by Capillary Electrophoresis,
Carmen Garcia-Ruiz et al. describe the use of CE for the separation of ionic compounds with low molecular weight and sufficient water solubility, compounds typically difficult to determine by conventional GC techniques. The use of CE for the determination of herbicides, phenols, amines, dyes, and aromatic sulfonic acids is described. In Organic Analysis in Environmental Samples by Electrochemical Methods, Ignacio Naranjo-Rodriguez and Jose Luis Hidalgo-Hidalgo de Cisneros describe the use of differential voltammetry, stripping methods and electrochemical detection. The authors outline the use of electrochemical detection in regulatory methods in the US and Europe, and provide specifics for determination of aromatic amines, aromatic hydrocarbons, phenols, PCBs, and other nitrogen containing compounds. Janet MacFall and Tony Riberio describe the use of nuclear magnetic resonance (NMR) spectroscopy in Nuclear Magnetic Resonance for Environmental Monitoring. NMR can be used for direct determination of samples, such as plants and soils, for analytes including pesticides, phosphorus, and water. Field application for study of soils is also described.

Analysis of organic compounds in the environment can also be categorized by compound class. The following series of articles reviews methodology for the determination of organic compound classes of particular environmental concern. In Trihalomethanes in Water, Analysis of, Louis Lepine and Roland Gilbert compare the primary analytical methods used for determining trihalomethanes in drinking water, key regulated analytes resulting from water disinfection with chlorine. The authors compare direct aqueous injection GC, liquid–liquid extraction with GC analysis, headspace GC, and purge and trap GC. An alternative disinfectant to chlorine for drinking water is the use of chloramine, frequently used to reduce the formation of trihalomethanes. However, chloramine can lead to the formation of cyanogen chloride, as discussed by Yufeng Xie and Cordelia Hwang, in their article, Cyanogen Chloride and Cyanogen Bromide Analysis in Drinking Water. The authors outline the use of purge and trap GC/MS, headspace GC with electron capture detection, and liquid–liquid extraction methods.

Billions of pounds of dyes are used globally each year, as discussed by J. Riu and D. Barcelo in their submission entitled Dyes, Environmental Analysis of. Because of the nonvolatile nature of most dyes, LC/MS is commonly used for their analysis. The authors discuss thermospray LC/MS applications and the use of atmospheric pressure ionization interfaces. CE is also discussed for analysis of sulfonated azo dyes.

In his paper, Explosives Analysis in the Environment, Bruce Tomkins, describes the use of liquid–liquid extraction followed by high-performance liquid chromatography (HPLC) analysis for the determination of explosives in aqueous samples and reviews the use of USEPA Method 8330 for the determination of explosives in soils. Field screening techniques, such as colorimetric and antibody based tests, are evaluated and the metabolism of explosives in the environment are reviewed. Torsten Schmidt et al. review the Nitroaromatics, Environmental Analysis of. The relevant USEPA and other regulatory agency methods are cited and their application discussed. Sample preparation procedures for water, soil, and particulate samples are reviewed. In situ analytical methods including electrochemical, immunoassays and sensors are described, as well as laboratory analysis via GC, GC/MS, and HPLC.

Phenols, Environmental Analysis of is reviewed by S.S. Srivastava and K. Maharaj Kumari. Colorimetric spot test, titrimetric, polarographic, and chromatographic methods, including GC, GC/MS, and HPLC, are discussed, as well as infrared and Fourier transform infrared analysis for formaldehyde in air samples.

Phenolic compounds are found both in nature and from industrial production, and phenol itself has been used as a disinfectant since 1865. Monika Moeder in Phenols Analysis in Environmental Samples, discusses the uses and toxocologic importance of phenols and regulations impacting their use and disposal. The commonly used analytical techniques for phenol determination are reviewed, including GC/FID (gas chromatography/flame ionization detector), GC/ECD (gas chromatography/electron capture detection), and GC/MS. The author also reviews the colorimetric method commonly used for determination of phenols as a group, normally referred to as ‘total phenol’. The application of different sample preparation procedures to various matrices is discussed and conventional techniques are compared with new developments in biosensors and immunoassay.

Michael Fisher and Israel Schechter have contributed a review of Polynuclear Aromatic Hydrocarbons Analysis in Environmental Samples, beginning with a definition of PAHs and their importance in the environment. Various extraction procedures, including Soxhlet, ultrasonic, supercritical fluid, and microwave assisted are reviewed for use in PAH analysis, followed by solid phase extraction and gel permeation chromatography clean-up procedures. Analysis by GC, HPLC, GC/MS, and optical methods is discussed, as well as recent procedure utilizing immunoassay techniques. Andres D. Campiglia reviews the determination of PAHs by luminescence techniques, in the article entitled Luminescence in Environmental Analysis. The author compares fluorimetry, phosphorimetry, and Shpol’skii spectrometry and their use for the determination of PAHs both in the laboratory and using laser excitation for field and remote analysis.
Another group of organic compounds of common interest in environmental analysis is the PCBs, consisting of 209 separate isomers. This topic is reviewed in *Polychlorinated Biphenyls Analysis in Environmental Samples* by Bert van Bavel et al. The authors provide a short history of PCB analysis in environmental samples and discuss the two most commonly used analytical methods, GC with electron capture detection and GC/MS. Procedures are reviewed for sample clean-up and fat removal and for sample extraction from a variety of matrices. Recent developments in SFE coupled to LC and GC coupled to time of flight MS are also reviewed.

The ability to rapidly determine parameters of environmental interest, especially in the field, is of particular interest both to provide direction in sampling of potentially contaminated sites and to minimize the number of samples requiring more time consuming and costly analysis back in the laboratory. The next three articles provide insight into recent developments in techniques for rapid deployment in the field. First, in *Volatile Organic Compounds in Groundwater, Probes for the Analysis of*, B.M. Patterson and G.B. Davis describe the use of VOC probes for the determination of petroleum products and chlorinated solvents in groundwater in the field. The authors provide a review of alternative field methods for VOCs and comparison with the VOC probes, based on a coil of silicone tubing, are given for actual field samples. The advantages of the VOC probes include exclusion of high molecular weight organic compounds from the sample, elimination of the need to collect, transport, and store samples, and higher sensitivity vs. conventional methods. Disadvantages include a lack of specificity due to the nature of the sensor currently used.

The analysis of dioxin and similar compounds has been of primary interest to the environmental analyst for a number of years. Traditional methods of analysis require extensive sample clean up and pre-concentration techniques, followed by highly specific GC/MS analysis, in order to attain the detection limits required for this class of compounds. Nigel Bunce and John Petrulis describe an alternative screening technique in their article entitled *Dioxin-like Compounds, Screening Assays*. The use of bioassay methodology, such as receptor-ligand binding assays, saturation assays, gel retardation assays, competition assays, and others are described and their applications for the determination of dioxin like compounds are reviewed. While bioassays cannot replace direct analysis techniques due to the lack of chemical identification, they can provide rapid, expensive screening to help eliminate negative samples from requiring further analysis. Barry Lesnik in *Immunosassay Techniques in Environmental Analyses*, discusses the broader application of immunoassay techniques. The author describes the USEPA interest in these rapid screening methods and provides a background on the development of methods within the USEPA in general and for immunoassay methods in particular. The use of enzyme linked immunosorbent assay (ELISA) for the determination of PCB contamination is described, including a discussion on specificity. Alternative immunoassay techniques are described for determination of dioxins, furans, PAHs, and explosives. Specific considerations for immunoassay method development are presented as well as method validation criteria and a summary of current USEPA methods development programs.

Determination of whether or not a waste is hazardous is of key interest in determining appropriate disposal procedures. Several methods have been developed by the USEPA and others in order to classify wastes as hazardous. In *Waste Extraction Procedures*, Barton Simmons describes the history of the development of waste characterization procedures, including the Extraction Procedure and subsequent Toxicity Characteristic Leaching Procedure. Leachate preparation and analysis is described, including the use of the zero headspace extractor. The author also describes alternative waste characterization procedures, including the Synthetic Precipitation Leaching Procedure, batch, sequential, and multiple extraction techniques. Limitations encountered with various waste extract procedures are also discussed.

The final article of this section, entitled *Underground Fuel Spills, Source Identification*, was contributed by Barry K. Lavine et al. The widespread use of underground fuel storage tanks throughout the USA has lead to numerous problems with leakage and subsequent contamination of groundwater and drinking water supplies. The authors describe the pattern recognition process used to categorize spills, and its use for fuel spill identification, incorporating principal component analysis to reduce the number of independent variables. Case studies are provided to demonstrate the use of the pattern recognition techniques to identify the source of jet fuel spills, based on GC analysis of the samples.

The comprehensive use of asbestos in approximately 3000 industrial applications in the past requires asbestos analysis at present and in the future. The different analysis methods range from simple and cost-effective procedures in order to decide whether asbestos is present up to the expensive and time-consuming determination of low fiber number concentrations of asbestos fibers including the identification of the fiber type using highly sophisticated measurement equipment.

The following survey discusses the most relevant objectives of asbestos analysis and the measurement techniques that are applied:

- Ambient/indoor air measurements – low concentration range, fiber type usually not known, identification required – using transmission electron microscopy (TEM) in combination with energy-dispersive X-ray analysis (EDXA) and selected area electron diffraction (SAED), and using scanning electron microscopy (SEM) in combination with EDXA.
- Workplace air measurements – low to high concentration range, fiber type usually known, identification possibly required – using SEM, TEM, and phase contrast optical microscopy (PCOM).
- Stationary source emission measurements using SEM, TEM, and PCOM.
- Bulk material analysis – usually qualitative measurements; semiquantitative or quantitative results possible, if required – using SEM, TEM, infrared (IR) spectroscopy, PCOM, polarized light microscopy (PLM), and X-ray diffraction (XRD).
- Water analysis using TEM.

1 INTRODUCTION

The combination of ideal technical properties (heat resistance, noncombustibility, high tensile strength, flexibility, resistance to chemical agents) has favored the use of asbestos in approximately 3000 industrial applications so that it plays an important role in modern civilization. These applications have been widely used because asbestos is an abundant, relatively inexpensive and nearly indestructible material, having unique properties that made it readily adaptable to a variety of physical forms and applications. Applications of asbestos comprise numerous building materials (for example loose-fill insulation, acoustic and thermal sprays, pipe and boiler wraps, flooring and roofing materials, cementitious products), friction plates, sealings, gaskets, heat-resistant clothing, adhesives, paints, coatings, etc.

Asbestos is the commercial term applied to the asbestiform varieties of six different silicate minerals. The asbestiform habit causes them to be easily separated

into long, thin, flexible, and strong fibers when crushed or processed. The names, ideal composition and Chemical Abstracts Service (CAS) numbers of these varieties are given in Table 1. Chrysotile is a fibrous mineral variety of serpentine. The five other asbestiform varieties belong to the amphibole group. The most important asbestos type is chrysotile, with about 94% of the worldwide production. Crocidolite has a share of 3–4% and amosite approximately 2% of the worldwide asbestos production. The other types play no significant role.

Industrial manufacturing of asbestos commenced in the middle of the nineteenth century. It was much later when medical research revealed the casual relationship between the inhalation of asbestos fibers and several severe diseases. Inhaled asbestos fibers can affect human health by causing conditions such as asbestosis and the growth of malignant tumors such as mesothelioma or lung cancer. Asbestos is now considered to be a costly mineral when all subsequent costs for its removal and occupational disease-related expenditure are taken into account. The health risks of asbestos fibers have highlighted the need for efficient measurement techniques.

Medical evidence indicates that the numerical fiber concentration, the fiber size, and the fiber type (biopersistence) are the relevant parameters for the evaluation of inhalation hazards. Fibers longer than 5 µm, narrower than 3 µm and with an aspect ratio greater than 3:1 are considered to be critical. A fiber counting and measuring technique is the logical approach, i.e. using microscopy methods. If positive identification of the fiber type is required, the only possible method is electron microscopy in combination with other identification systems, in order to discriminate between asbestos and nonasbestos fibers (for example naturally occurring or man-made mineral fibers (MMMFs)).

A variety of methods, using technical equipment of different levels of complexity and investment (operating) costs, have been developed to satisfy the recent requirements of science and legislation:

- comparison with exposure limits;
- monitoring airborne fiber concentrations (ambient, indoor air, stationary source emissions);
- final clearance monitoring in connection with asbestos abatement in buildings;
- bulk material analysis.

In order to provide comparability between measurements, standard methods are required. This report only deals with methods that have undergone or will undergo future standardization by a national or international standards organisation (e.g. International Organization for Standardization (ISO)) or other institutions with regulation purposes (e.g. World Health Organization (WHO), United States Environmental Protection Agency (USEPA), Verein Deutscher Ingenieure (VDI)). Specific applications, as for example the determination of asbestos fibers in lung tissue, are not dealt with. Table 2 gives a survey of the proven and established methods.

\(^a\) The detection limit can be varied when varying the analysis conditions (e.g. the evaluated filter area).
1. Concentration (fibers/per cubic meter) of airborne asbestos fibers:
   (a) assessment of concentrations of airborne fibers in workplace atmosphere (comparison with occupational exposure limits; most commonly personal exposures);
   (b) assessment of concentrations of airborne fibers in ambient air (background concentrations);
   (c) assessment of concentrations of airborne fibers in emissions from stationary sources (assessing the effectiveness of process-control techniques and monitoring the effects of process modifications);
   (d) assessment of concentrations of airborne fibers in indoor air – sources of contamination, status quo measurement, assessment of the progress of abatement measures, final clearance monitoring;
   (e) epidemiology.

2. Mass concentration (milligrams per cubic meter) of asbestos fibers:
   (a) assessment of concentrations of airborne fibers in workplace atmospheres (most commonly personal exposures);
   (b) assessment of concentrations of airborne fibers in emissions from stationary sources.

3. Indicative or qualitative determination of asbestos in bulk materials.

   Today the greater part of measurements for asbestos analysis concerns indoor air measurements, workplace measurements, and bulk sample analysis. Ambient air measurements no longer play a significant role in countries where the use of asbestos has been drastically restricted by law. The situation may be different in countries with lower restriction levels.

3 DETERMINATION OF AIRBORNE ASBESTOS FIBERS

3.1 General

Measurement tasks that can be solved by a pure fiber count commonly use PCOM. Such situations are frequently observed in workplace atmospheres of asbestos processing industries, where most fibers are asbestos.

In cases where identification of fiber type is needed the PLM technique can be used so long as the fibers are wider than about 1 µm.

Electron microscopy techniques (SEM, TEM) are more expensive but they provide additional information on fiber type. SEM, in conjunction with EDXA, can generally be used to determine the elemental composition of fibers wider than about 0.1 µm. The most expensive method, TEM, is generally acknowledged as the most accurate technique for characterizing crystalline inorganic fibers and can be used to provide chemical and structural information for fibers down to about 0.01 µm in width. The results of the different microscopic methods, which provide fiber concentrations, are not directly comparable, because the methods differ in sample preparation and evaluation, and partially in fiber counting rules.

Each measurement technique used gives an index for the numerical concentration of a certain fiber type. Some techniques may give lower counts, resulting from lower visibility caused by lower magnification or resolution; some may give higher counts due to false positive identification connected with the limits of the identification method used. Some problems related to the use of automatic image analysis systems for fiber counting purposes have yet to be resolved, so that this modern technique cannot yet replace the microscope operator.

The technical specifications and a detailed description of sampling, sample preparation, and sample evaluation are beyond the scope of this article and are given in the standards or other technical rules which are referenced.

3.2 Scanning Electron Microscopy

SEM, in combination with EDXA, enables the detection of fibers and the establishment of their elemental composition. Thus fibers may be classified, usually as chrysotile, amphibole asbestos, other inorganic fibers, or calcium sulfate fibers. This method is used to determine asbestos in air samples (ambient, indoor, and workplace air; section 3.2.1) and in bulk material samples (section 4.4). Figure 1 shows a modern SEM set-up.
3.2.1 Principle

A sample of airborne particulate is collected by drawing a measured volume of air through a gold-coated capillary-pore membrane filter (polycarbonate filter, diameter usually 25 mm) with a nominal pore size of 0.8 µm. Figure 2 shows an appropriate sampling apparatus in two different working environments.

The sampled volume depends on the objective of measurement. Usually it is 2 L min\(^{-1}\) per square centimeter of filter area over a period of 8 h. The dust-loaded filter is treated in a plasma asher (oxygen plasma) to remove organic particles that could interfere with the detection and analysis of the asbestos fibers.

Figure 3 shows a plasma asher, whereas Figure 4 shows a filter loading before and after plasma ashing treatment of a sample of airborne dust.

The filter is then examined in the SEM. The individual fibrous particles and constituent fibers in a randomly selected area of the filter (the total area of the randomly distributed image fields is 1 mm\(^2\)) are then counted at a defined magnification (for example 2000\(\times\)) according to defined counting rules. The fiber is then examined at a higher magnification (for example 10 000\(\times\)) to measure its dimensions and to determine its elemental composition using EDXA. The fiber data are recorded and the fiber classified accordingly.

Figures 5 and 6 show some examples of asbestos fibers on the filter surface, indicating the geometric dimensions and the corresponding EDXA spectra.

3.2.2 Characteristics

The range of concentrations for fibers greater than 5 µm in length and within the range of diameters that can be detected and measured under standard
measurement conditions, is approximately 3–200 fibers per square millimeter of filter area. The air concentrations represented by these values are a function of the volume of air sampled.

The ability of the method to detect and classify fibers less than 0.2 µm in diameter is limited. If airborne fibers are predominantly less than 0.2 µm in diameter, a TEM method, such as ISO 10312, can be used to determine the smaller fibers.

The detection limit is defined as the fiber concentration below which, with 95% confidence (Poisson distribution), no fibers are found during the SEM examination. The detection limit can be lowered by filtration of progressively larger volumes of air and by examination of a larger area of the specimen in the SEM. In practice, the lowest achievable detection limit for a particular area of SEM specimen examined is controlled by the total suspended particulate concentration remaining after the plasma ashing step.

A detection limit of approximately 300 fibers per cubic meter is obtained if an air volume of 1 m³ per square centimeter of filter surface area passes through the filter, and an area of 1 mm² of the filter area is examined.

3.3 Transmission Electron Microscopy

The TEM technique\(^\text{5,6}\) is applicable to the determination of airborne asbestos in ambient and indoor air, and for detailed evaluation of any atmosphere in which asbestos structures are likely to be present.

TEM is currently the only technique capable of unequivocal identification of the majority of individual fibers of asbestos. However, it requires expensive and time-consuming measurement effort. Subjective and instrumental factors contribute to this measurement, and consequently a very precise definition is required of the procedure for identification and enumeration of asbestos. The sample preparation technique depends on the objective of measurement, i.e. whether the intention is to determine the concentration of airborne asbestos-containing structures or the asbestos fiber potential by disentangling the structures.

Airborne asbestos-containing structures comprise single fibers, fiber bundles, and even very complex and aggregated structures which may also be aggregated with other particles. The number of asbestos fibers and bundles incorporated in these complex structures can exceed the number of isolated fibers and bundles observed, and many of them may be completely obscured in direct-transfer sample preparations.\(^\text{5}\) With the indirect-transfer preparation technique\(^\text{6}\) organic and water-soluble materials are removed and the complex structures are dispersed via a liquid phase into their individual component fibers and bundles, hence giving a higher fiber count than direct transfer methods. However, the sample preparation effort is increased.

3.3.1 Direct-transfer Method

A sample of airborne particulate is collected by drawing a measured volume of air through either a capillary-pore polycarbonate membrane filter of maximum pore size of 0.4 µm or a cellulose-ester (either mixed esters of cellulose or cellulose nitrate) membrane filter of maximum pore size 0.45 µm by means of a pump. The choice of filter type determines the sampling pump required, as capillary-pore polycarbonate membrane filters produce a higher pressure drop than do cellulose-ester membrane filters.

TEM specimens are prepared from polycarbonate filters by applying a thin film of carbon to the filter surface by vacuum evaporation. Small areas are cut from the carbon-coated filter, supported on TEM specimen grids, and the filter medium is eliminated by a solvent extraction procedure (usually a Jaffe washer using chloroform (CAS 67-66-3) or\(^\text{6}\) \(N\)-methyl-2-pyrrolidone (CAS 872-50-4) as the solvent). This procedure leaves a thin film of carbon which bridges the openings in the TEM specimen grid, and which supports each particle from the original filter in its original position.

in the SEM. This corresponds to an evaluated sample air volume of 0.01 m\(^3\). Under these conditions a single detected fiber on the filter corresponds to 100 fibers per cubic meter.

This method had been developed and optimized as being cost-effective, economical to perform, and satisfying the needs of epidemiological research. The major goal concerning air quality characteristics was to provide a measurable result that reflects the concentration of airborne structures with the dimensions of the critical fiber (section 1).

Figure 6 EDXA spectra of (a) crocidolite, (b) chrysotile, and (c) amosite.
Cellulose ester filters are chemically treated (using a mixture of dimethylformamide (CAS 68-12-2), glacial acetic acid (CAS 64-19-7) and water) to collapse the pore structure of the filter. The surface of the collapsed filter is then etched in an oxygen plasma to ensure that all particles are exposed. A thin film of carbon is evaporated on to the filter surface and small areas are cut from the filter. These sections are supported on TEM specimen grids and the filter medium is dissolved away by a solvent extraction procedure (usually a Jaffe washer using dimethylformamide or acetone (CAS 67-64-1) as solvent).

The TEM specimen grids undergo a quantitative structure count on randomly selected grid openings (magnification 20 000×; lower magnifications can be used when larger objects, such as fibers longer than 5 μm, are to be determined). In the TEM analysis, ED is used to examine the crystal structure of a fiber, and its elemental composition is determined by EDXA. The analysis results are used to classify the fiber. The fiber classification procedure is based on successive inspection of the morphology, the ED pattern for a selected area, and the qualitative and quantitative EDXA. The identification of chrysotile is confirmed only by quantitative ED, and amphibole is confirmed only by quantitative EDXA and quantitative zone axis ED.

The lengths and widths of all classified structures are recorded. The number of asbestos structures found on a known area of the microscope sample, together with the equivalent volume of air filtered through this area, is used to calculate the airborne concentration in asbestos structures per liter of air.

3.3.2 Indirect-transfer Method

A sample of airborne particulate is collected by drawing a measured volume of air through either a capillary-pore polycarbonate membrane filter of maximum pore size 0.4 μm or a cellulose-ester (either mixed esters of cellulose or cellulose nitrate) membrane filter of maximum pore size 0.8 μm by means of a pump. The choice of the filter type determines the sampling pump required as capillary-pore polycarbonate membrane filters produce a higher pressure drop than do cellulose-ester membrane filters.

A portion of the filter is ashed in an oxygen plasma, and the residual ash is dispersed in distilled water with pH adjustment to between 3 and 4 using acetic acid. Analytical filters are then prepared by filtration of known volumes of this aqueous dispersion through either capillary-pore polycarbonate membrane filters of maximum pore size 0.2 μm or cellulose-ester membrane filters of maximum pore size 0.22 μm.

TEM specimens are prepared from polycarbonate analytical filters by applying a thin film of carbon to the filter surface by vacuum evaporation. Small areas are cut from the carbon-coated filter, supported on TEM specimen grids, and the filter medium is dissolved by a solvent extraction procedure with an organic solvent (usually a Jaffe washer using chloroform or N-methyl-2-pyrrolidone as solvent). This procedure leaves a thin film of carbon which bridges the openings in the TEM specimen grid, and which supports each particle from the original filter in its original position.

Cellulose ester filters are chemically treated (using a mixture of dimethylformamide, glacial acetic acid, and water) to collapse the pore structure of the filter, and the surface of the collapsed filter is then etched in an oxygen plasma to ensure that all particles are exposed. A thin film of carbon is evaporated on to the filter surface and small areas are cut from the filter. These sections are supported on TEM specimen grids and the filter medium is dissolved away by a solvent extraction procedure (usually a Jaffe washer using dimethylformamide or acetone as solvent).

A quantitative fiber count on randomly selected grid openings is carried out at a magnification of approximately 20 000× (or less, depending on the fiber size/diameter spectrum to be analyzed). In TEM analysis, ED is used to examine the crystal structure of a fiber, and its elemental composition is determined by EDXA. The results are used to classify the fibers. The fiber classification procedure is based on successive inspection of the morphology, the selected area ED pattern, and qualitative and quantitative EDXA.

The lengths and widths of all classified structures are recorded. The number of asbestos structures found on a known area of the microscope sample, together with the volume of air filtered through the sample collection filter that was ashed, the proportion of the aqueous dispersion that was filtered, and the area of the analytical filter are used to calculate the airborne concentration of asbestos in asbestos structures per liter of air.

The examination consists of a count of the asbestos structures present on a specified number of grid openings. Fibers are classified into groups on the basis of morphological observations, ED patterns, and EDXA spectra. The total number of structures to be counted depends on the statistical precision desired. In the absence of asbestos structures, the area of the TEM specimen grids that must be examined depends on the analytical sensitivity required.

3.3.3 Characteristics

The upper limit for the range of concentrations that can be measured on the analytical filter is 7000 structures per square millimeter. The air concentrations represented by this value are a function of the volume of air sampled and the degree of dilution or concentration selected during the specimen preparation procedures. A minimum length of
0.5 µm has been proved to be a reasonable lower limit to the dimensions of asbestos fibers that should be recorded. In theory the detection limit can be lowered indefinitely by filtration of progressively larger volumes of air, concentrating the sample during specimen preparation (indirect-transfer method), and by extending the area to be examined. In practice, the lowest achievable detection limit for a particular area of TEM specimen examined is controlled by the total suspended particulate concentration remaining after ashing and aqueous dispersal steps. In order to achieve lower detection limits for critical fibers (section 1), lower magnifications permit more rapid examinations of larger areas of the TEM specimens when the examination is limited to these dimensions of fiber.

3.4 Phase Contrast Optical Microscopy

The PCOM method,(7–9) despite its limitations concerning visibility and identification, is well-proven for widespread international use in the field of occupational hygiene and measurement of asbestos emissions from stationary sources.

3.4.1 Principle*

A sample is collected by drawing a known volume of air through a membrane filter (membrane of mixed esters or cellulose nitrate, 0.8–1.2 µm pore size) by means of a pump. The filter is exposed to acetone vapor, which condenses on the filter, collapsing its pores and making it transparent. Different methods are described for this procedure.(7–9) The filter is then fixed to a glass slide, where it appears as a transparent and uniform plastic film with any fibers on the upper surface. A liquid must be added to provide optimal contrast – if the refractive index of the fibers exceeds 1.51 then triacetin (glycerol triacetate, CAS 102-76-1) is satisfactory; for inorganic fibers with refractive indices less than 1.51 the filter surface must be etched to expose the fibers using a plasma ash. Distilled water is then used as the contrast liquid. Fibers on a measured area of the filter are counted visually using PCOM with a magnification of 400–600, and the concentration of fibers in the volume of air sampled is calculated.

3.4.2 Characteristics*

This method is usually used to measure the fiber concentration of airborne structures present with the critical dimensions length greater than 5 µm, diameter less than 3 µm, and aspect ratio greater than 3:1. The minimum visible width depends on the resolving power of the optical system, the difference in refractive index between the fiber and the contrast liquid and – as for all fiber counting methods – the visual acuity of the microscopist. Thus the limit of visibility can be as low as about 0.15 µm, but is usually higher in practice. The detection limit depends on the extent of sampling and evaluation, and especially the blank value of the analytical filters. The practical limit is 10,000 fibers per square meter or higher.

The method does not permit the determination of the chemical composition or crystallographic structure of fibers, and therefore cannot be used to discriminate between different fiber types. Supplementary information on fiber type may be obtained by using other methods, such as PLM, SEM, or TEM.

4 DETERMINATION OF ASBESTOS IN BULK MATERIALS

4.1 General

The comprehensive use of asbestos in the past has produced the present-day need to identify and possibly quantify asbestos in a variety of asbestos-containing industrial products. These include building materials such as loose-fill insulation, pipe and boiler wraps, plasters, paints, flooring products, roofing materials, and cementitious products. The diversity of these bulk materials necessitates the use of several different methods of sample preparation and analysis.(10) Figure 7 shows SEM images of different asbestos-containing products.

A precondition for a reliable analytical result is a representative sample of the materials of interest.(11) Many manufactured products containing asbestos, such as boards, sheets, cement pipes, textiles, ropes, friction products, plastics, and vinyls can be assumed to have the asbestos uniformly distributed throughout the material. Thus, a relatively small sample can be taken as being representative of the whole. Other products may be layered and the asbestos will be present in part of the cross-section. Insulation and spray materials tend to be more variable. Insulation was often wet-mixed on-site and subsequent repairs and patching may add to this variability. Samples should be taken that are representative of the whole material.

The sample may require mechanical and/or chemical treatment in order to release fibers from any matrix and to remove adhering particles prior to fiber analysis (microscopic methods). Any preparation technique must preserve the integrity of morphology, structure, and chemistry of the fibrous particles. IR and XRD require careful homogenization of the sample.

The simplest analytical method is the use of a stereomicroscope which provides preliminary information on the sample and the fiber type. Stereomicroscopic analysis

* Reproduced by permission of WHO.
ASBESTOS ANALYSIS

Figure 7 SEM images of different asbestos-containing products: (a) sprayed-on insulation material, (b) asbestos cement, (c) floor covering (vinyl floor tile).

determines the homogeneity, texture, friability, color, and the extent of fibrous components of the sample. This information is then used as a guide to the selection of further, more definitive qualitative and quantitative asbestos analysis methods.

Qualitative and semiquantitative results may be obtained by additional analyses, such as PLM, XRD, analytical electron microscopy (AEM), or IR spectroscopy.

The accuracy, precision, and detection limits of the different analytical techniques for bulk material analysis are dependent on the type of sample (matrix, components, texture, etc.), the preparation of the sample (homogeneity, grain size, etc.), and the specifics of the method.

4.2 Polarized Light Microscopy

Samples are examined using PLM to determine optical properties of constituents and to provide positive identification of suspect fibers. The major goal of the qualitative preparation is to mount easily visible representative fibers or fiber bundles in appropriate refractive index liquids on microscope slides for complete optical characterization. A tentative identification based on the stereomicroscopy evaluation or other preinformation is used to select the most appropriate mounting liquid. Identification of a single asbestos fiber as one of the six regulated asbestos types requires assessment of the following optical properties using PLM with magnifications from about 80 upwards, as appropriate:

- morphology
- color and pleochroism (if present)
- birefringence
- extinction characteristics
- sign of elongation
- refractive index assessment.

Identification is based on comparing the recorded observations (morphology, optical properties) on the analyzed fibers against the properties of asbestos reference standards. A close match between the optical properties of the sample fiber and the asbestos standard will normally be achieved.

Figures 8–10 show the application of PLM to asbestos identification. The semiquantitative estimation of the asbestos content in a sample is possible.

4.3 X-ray Diffraction

In powder XRD analysis, a bulk sample of material is subjected to X-ray radiation and the angle of the diffracted radiation is measured. The solid powdered crystalline sample will diffract the incident beam of parallel, monochromatic X-rays whenever Bragg’s law is satisfied for a particular set of planes in the crystal lattice. A diffraction pattern is generated which is a characteristic of the structure of the crystalline phases present.

This technique allows determination of the crystal structure of mineral compounds. However, XRD cannot determine crystal morphology. Therefore in asbestos
Figure 8 Chrysotile fiber bundles in cinnamic acid ethyl ester; positive phase contrast; fibers parallel to polarizer are blue with orange-red halo.

Figure 9 Chrysotile fiber bundles and MMMF (thick bent object) in cinnamic acid ethyl ester; positive phase contrast; fibers parallel to polarizer are blue with orange-red halo; the MMMF shows no optical effects.

analysis, it is not possible to distinguish between fibrous and nonfibrous forms of serpentine and amphibole minerals using XRD. XRD should be used in conjunction with other methods, such as PLM or electron microscopy, and thus can provide a reliable analytical method for the identification (diffraction pattern), characterization, and quantitation (signal intensities) of asbestiform minerals in bulk materials. In order to identify the minerals the diffraction patterns should be compared with powder diffraction patterns of well-characterized reference materials.

Quantitative results require calibration. Accurate quantitative analysis of asbestos in bulk samples by XRD is critically dependent on particle size distribution, crystallite size, preferred orientation and matrix absorption effects, and comparability of standard reference and sample materials.

Figure 10 Birefringence: (a) chrysotile fibers are clearly visible between crossed polars, whereas the isotropic MMMF is not visible; (b) with the first-order red compensator the chrysotile fibers appear blue or yellow, depending on their orientation with respect to the polarizer, and the MMMF is visible.

Figure 11 shows the XRD spectra of the six different asbestos types. The samples were prepared for routine qualitative analysis.

4.4 Analytical Electron Microscopy

Both SEM\(^{(14)}\) and TEM\(^{(10)}\) can be used to examine bulk material samples, the latter being more expensive and time-consuming.

The preliminary visual inspection and examination of the material using the stereomicroscope served to identify representative or relevant portions which are prepared as samples for SEM. SEM allows a direct investigation of the surface of the sample, even if the surface is highly structured. The sample is mounted on
the sample holder or sputtered with carbon or gold. The sample is examined with respect to asbestos fibers initially with low (20–50), then with high (500–2000) magnification. Negative results have to be verified with a magnification of 5000–10,000. Detected fibers are assessed morphologically, and the elemental composition is determined using EDXA. Based on these analytical results the fibers are classified or even identified. SEM is very useful for observing surface features in complex particles, and for determining elemental compositions.
The application of TEM to bulk material analysis has been described in detail. The sample material is treated by ashing or dissolution or, when this is not possible, at least by grinding or milling. The material is then dispersed in an organic solvent. A small volume of this suspension is transferred to the top of a carbon-coated TEM grid, the solvent is evaporated, and the grid examined for qualitative and semiquantitative analysis. Quantitative evaluation requires some additional procedural steps. A known weight of the bulk sample, after preparation, is dispersed in distilled water, filtered (see section 5) and TEM grids are prepared from appropriately loaded filters using the standard methods.

4.5 Infrared Absorption
This technique indicates the possible presence of certain functional groups in the components analyzed but cannot distinguish between fibers and other material with the same chemical properties. The resonant absorption of IR radiation is measured for peaks indicative of various functional groups.

Chrysotile shows a characteristic double band in the near IR at about 3660 and 3700 cm\(^{-1}\) (OH stretching vibrations). The intensity of the latter is used for quantitation.

The IR spectra of the amphibole asbestos types are quite similar. A group of characteristic bands is found in the mid- and far IR in the wavenumber range between 300 and 1200 cm\(^{-1}\). The absorption band at 780 cm\(^{-1}\) has proved best for the quantitation of crocidolite and amosite. Figure 12 shows the IR spectra of chrysotile, crocidolite, and amosite. The IR method is proven only for these three asbestos types.

Solid samples are prepared as follows. The powdered sample is homogeneously mixed with potassium bromide (CAS 7758-02-3) and pressed to form a transparent pellet. The IR spectrum of the sample is recorded in the range between about 250 and 4000 cm\(^{-1}\).

As IR spectra do not contain any information about morphological structures, it is useful to verify the presence of fibrous structures using a light microscope, if IR indicates the presence of asbestos—especially amphibole—so as to avoid false positive identification as far as possible.

5 DETERMINATION OF ASBESTOS FIBERS IN DRINKING WATER
Asbestos cement pipes, used within drinking water supply networks, also need to be considered critically. Fiber release from this type of pipe depends on the condition of the material matrix and surface and also on the characteristics of the water, especially its saturation index. When the water is around saturation with respect to calcium carbonate, the fiber release tends to a minimum.

Due to the variety of fibrous particles in water, a method is required that allows identification of the fiber type and the visibility of fibrils at least 0.5 µm in length. Thus TEM, including EDXA and SAED, is the preferred method (section 3.3). SAED allows the identification of particles of organic origin that cannot be ashed, such as specific parts of diatoms or excretions of iron-accumulating microorganisms. The recommended characteristics are:

- membrane filter pore size 0.2 µm;
- magnification 10 000;
- analytical sensitivity 3300 fibers per liter (corresponding to one detected fiber);
- detection limit 10 000 fibers per liter.

Health risks as a result of oral uptake of asbestos fibers from drinking water are not evident so far. Consequently WHO does not recommend a limiting value for asbestos fibers in drinking water.

6 QUALITY ASSURANCE
Usual and adequate intralaboratory quality assurance measures with respect to qualified personnel, laboratory equipment, reference material, etc. can be based on the standard EN 45001 or the draft standard ISO/IEC.
In addition, an essential part of quality assurance for fiber-counting methods is the performance of counting checks because of the large differences in results obtained within and between laboratories using microscopical counting. In practice, the effects of chance superimposition on counting results are small compared with effects due to differences between individual microscopists. Laboratories using fiber-counting methods should participate in a national or international proficiency testing scheme in order to minimize interlaboratory variation. Interlaboratory exchange and verification of samples can further complement internal quality control.

The purpose of the quality assurance program is to minimize failures in the analysis of materials prior to submitting the results to the client. Failures in the analysis of asbestos materials include false positives, false negatives, and misidentification of asbestos types. False positives result from identification or quantitation errors. False negatives result from identification or quantitation errors. False negatives result from identification, detection, or quantitation errors.

Atomic fluorescence is a spectroscopic process which is based upon the absorption of radiation of a certain wavelength by an atomic vapor and subsequent radiational deactivation of the excited atoms toward the detection device. Both the absorption and the subsequent atomic emission processes occur at wavelengths which are characteristic of the atomic species present. Atomic fluorescence spectroscopy (AFS) is a very sensitive and selective method for the determination of a number of environmentally and biomedically important elements such as mercury, arsenic, selenium, bismuth, antimony, tellurium, lead, and cadmium. This technique has become one of the most important analytical tools for trace element analysis in environmental samples, such as mercury, owing to its advantages over other methods in terms of linearity and detection levels. Several books and a number of book chapters and review articles have been published dealing with the theory and instrumentation of AFS. This article will provide up-to-date AFS information regarding its application in environmental analysis.

1 THEORETICAL ASPECTS

1.1 Types of Atomic Fluorescence

The main types of atomic fluorescence process are illustrated in Figure 1(a–c), which shows diagrammatically the transitions involved. Resonance fluorescence occurs when atoms absorb and re-emit radiation of the same wavelength (Figure 1a). Many of the measurements made by analytical chemists employing AFS involve this type of fluorescence. The most analytically useful fluorescence line is the resonance fluorescence corresponding to the transition between an electronic excited state and the ground state of the atom.\(^1\) The wavelengths of the absorption (\(\lambda_A\)) and fluorescence (\(\lambda_F\)) can also be different. If the photon energy of fluorescence is less than the photon energy of absorption, i.e. \(\lambda_F > \lambda_A\), the process is called Stokes-type fluorescence. If the reverse is true, i.e. \(\lambda_F < \lambda_A\), this process is called anti-Stokes type fluorescence.\(^1–3\)

Direct line fluorescence is nonresonance fluorescence, which is observed when a common upper level is involved for both excitation and fluorescence. Figure 1(b) shows an example of direct line fluorescence in which an atom is excited from the ground state to a higher excited electronic state and then undergoes a direct radiational transition to a metastable level above the ground state. Stepwise line fluorescence (Figure 1c) occurs when the upper energy levels of the exciting and of the fluorescence line are different. The excited atoms may undergo deactivation, usually by collision, to a lower excited state rather than return directly to the ground state. There are several more fluorescence lines which are not of much analytical use. Details about those fluorescence lines can be found in the literature.\(^1–6\)

Generally, an atomic fluorescence spectrum consists of only a few lines because not all of these fluorescence-generating processes are active simultaneously.\(^6\) Therefore, the atomic fluorescence spectrum is much simpler than the one obtained using atomic emission spectroscopy (AES).

1.2 Intensity of Fluorescence Radiance

It is beyond the scope of this article to provide details about the derivations of the intensity expressions. Only the results of the derivations will be given in order to understand the various dependences of the fluorescence signal. For a more comprehensive discussion and a complete derivation of the expressions, articles by Winefordner et al.\(^4,6,8\) can be highly recommended.

The intensity of the fluorescence radiation produced in a transition depends on a number of factors, the most important of which are\(^5,7\) (a) the intensity of the excitation source, (b) the concentration of the atom in
In the derivation of intensity expression, it has been assumed that the atom under consideration has only two energy levels, ground state (1) and first excited state (2). Other important assumptions are that the atoms are uniformly distributed in the atomizer and the concentration of the analyte atom is low, and the temperature of the atomizer and the radiation density of the source are spatially uniform. The fluorescence radiance can be given by Equation (1):

\[ B_F = \left( \frac{l}{4\pi} \right) Y_{21}E_{\nu_{12}} \int_0^\infty k_v \, dv \]  

where \( B_F \) is the absolute radiance; \( l \) is the pathlength in the direction of the detector; \( Y_{21} \) is the fluorescence power efficiency, \( E_{\nu_{12}} \) is the spectral irradiation of source at absorption line of frequency \( \nu_{12} \); and \( k_v \) is the absorption coefficient.

The integration term gives the integrated absorption coefficient over the absorption line, which is a function of the concentration in states (1) and (2), the statistical weights of state (1) and state (2), and the Einstein \( B_{12} \) absorption coefficient.

The above equation gives some analytically important information. The fluorescence radiance \( B_F \) is linearly dependent on the source irradiance and the fluorescence quantum efficiency of the transition as long as \( E_{\nu_{12}} \) is very much below the saturation value. Therefore, in order to obtain a large fluorescence signal it is necessary to use a highly irradiant light source. It can be further demonstrated that if the atomic concentration is low, \( B_F \) is linearly related to the total concentration of atoms in all states.

### 1.3 Quenching

The intensity of the atomic fluorescence can be diminished by the collision between excited atoms and other molecules in the atomization sources. This process is called quenching. This problem is accounted for by the inclusion of the term \( Y_{21} \) in the fluorescence radiance equation given above. Since the quenching process is very important in atomic fluorescence, a few examples are given below. For a more comprehensive discussion on quenching processes, the reader is referred to several good reviews.

1. The excess electronic energy of the excited atoms is converted into translational energy of the colliding species without involving the internal energy of the latter. For instance, this quenching can be processed by collision with free atoms (Equation 2):

\[ A^* + B \rightarrow A + B \]  

or with free electrons (Equation 3):

\[ A^* + e^- \rightarrow A + e^- \]  

2. The excess electronic energy of the excited atoms is released on collision, resulting in changes of the electronic or vibrational/rotational energy of the colliding species, for instance quenching by collision
with other atoms (Equation 4):

\[ A^* + B \rightarrow A + B^* \]  

(4)
